In discussing the paper, Dr. George Tucker Harrison, of New York, said that Dr. Stone treated puerperal malarial fever as too trivial a disease. It is a common complication or sequel of labor, although it is not always easy to determine the cause. It may occur even after a perfectly aseptic delivery, lasts for weeks or months, and is often followed by rheumatism. As to the removal of the uterine appendages, operations are often undertaken without a diagnosis having been made. No radical operation should be undertaken until every other means of relief has been tried, unless, of course, it is plain that the organs are structurally diseased. As to extra-uterine pregnancy, the operation should be performed early. Tait confounds hæmatocele and hæmatoma with extra-uterine pregnancy in his writings on the diagnosis of the condition.

Dr. Joseph Price, of Philadelphia, wished to emphasize Dr. Harrison's remarks as to operations upon the female pelvis. They should be undertaken only for an objective disease. Pelvic surgery has also suffered because many operations have been imperfectly done. The mortality from abdominal section for ovarian, tubal, and uterine diseases has been reduced to about two per cent., and the results of McGuire's suprapubic cystotomies conclusively show that simply opening the abdomen should not prove fatal. Dr. Coe, he said, had made some drawings of pus-tubes which are influencing professional opinion and action, but the drawings are unfortunately not true to nature. Dr. Price said that if the presence of pus in the tubes or pelvic cavity can be determined, it should be evacuated, as from any other part of the body. He advises that all forms of fibroids, even if small, be extirpated. Battey's operation, so far as it implies "normal ovariotomy," he said, should be consigned to oblivion. Dr. Price also condemns tampering with so-called intra-uterine medication by curettes, caustics, electricity, and sounds, and said that Emmet has not passed a sound for fifteen or twenty years. The palliative treatment of all intra-uterine diseases should be conducted on the most conservative principles. More prominence should be given to the ravages of gonorrhœa in unsuspecting wives as a cause of disease. He then spoke of extra-uterine pregnancy, advising operation as soon as the condition is recognized. He has found rupture of the pregnant tube to occur almost invariably near one of the fimbriated extremities.

Dr. Hunter McGuire corrected a statement of Dr. Harrison's. It was not Dr. Barker, but the late Dr. Otis F. Manson, of Richmond, who first described puerperal malarial fever.

With reference to the use of the uterine sound, Dr. McGuire said that he has never had the slightest reason to think that he has done harm by its use; on the contrary, he is sure he has often done good. As to Battey's operation, he believed that it would soon become obsolete. To take out a normal ovary for a neurotic trouble, hereafter, he thinks should be considered a crime. But when there are pathological changes in the organ, and when all other remedies have failed, then an operation to remove the ovaries or appendages, or anything in the female pelvis that is causing ill-health, is justifiable. He did not agree with Dr. Price that all fibroids should be removed.

Dr. Joseph Hoffman, of Philadelphia, said that it is a mistake to suppose that more than about one per cent. of diseases of women are essentially cellulitis. Tubal pus-cavities are like links of sausage; hence, to open one does not open all.

Dr. Edwin Ricketts, of Cincinnati, spoke of the history of abdominal sections, remarking that McDowell was born in Rockbridge County, Va., within a few miles of where the Society was assembled.

The tendency now, he said, is toward too much pelvic surgery, and it should never be forgotten that discredit comes upon surgery when the surgeon fails to make his diagnosis clear, and hence fails to give that benefit which the patient seeks.

Dr. Isaiah H. White, of Richmond, spoke especially of the importance of an early diagnosis of extra-uterine pregnancy, in order that an operation may be performed in time to avert the dangers ahead. But some cases pass through the stage of rupture and collapse, and the products of conception remain in a quiescent state until some additional cause of inflammatory or ulcerative action takes place, as, for instance, the occurrence of pregnancy. There are many cases in which extra-uterine pregnancy is first discovered years after impregnation, by reason of the escape of fœtal bones. Such cases suggest the propriety of the treatment recommended by some, viz., to kill the fœtus by electricity as soon as the diagnosis is clear, allowing the mass to become encapsulated and remain in the abdomen. What are known as the "remnants" of an extra-uterine pregnancy—excluding, of course, the fœtus itself—are most probably only the products of the inflammation excited by the passage of the fœtus through the tube into the peritoneal cavity. The appearance of the tube in cases of pyosalpinx, which reminds one of sausages, is due to the adhesive bands formed around the tube. Dr. McGuire was undoubtedly correct in deploring the so-called normal ovariotomy.

Dr. Landon Carter Gray, of New York, in response to requests for remarks, condemned Battey's operation for the cure of nervous diseases, just as he did Baker Brown's clitoridectomies, Sayre's wholesale circum-

cisions, and Stevens's general cutting of eye-muscles. In nearly all the cases in which such mutilations have been resorted to for the cure of nervous diseases, the relief that has followed in some cases has been of too short duration to justify the operations. These operations do good only upon the theory of mental impression. Esquirol recorded his tests as long ago as 1828, and why they are ignored now by men high in the profession Dr. Gray could not understand. Esquirol divided his epileptic patients into groups. To one group he gave one class of remedies, with the strong adjuvant of mental impression as to the benefit that would result; to a second group he gave another class of drugs, with the same adjuvant of mental encouragement; while to a third group he gave colored water, but with the same encouragements. Each group of cases did about equally well for a time; but relapses soon began to occur, and all the cases finally relapsed to their former condition. If an operation is to be performed simply to get the benefit of mental impression, let that operation be as slight as possible.

DR. WILLIAM W. PARKER, of Richmond, could not lay aside the education of a large experience which taught him that intra-uterine injections are perfectly safe if proper precautions are observed.

DR. HARRISON did not wish to put himself on record as wholly opposed to Battey's operation; for there are serious nervous troubles in which, although the ovaries are apparently only moderately diseased, the patient is permanently relieved, if not cured, by the operation. Dr. Battey's original error—which, however, has long since been corrected—consisted in naming his operation "*normal* ovariotomy."

DR. STONE, in closing the dissussion, said that, in his opinion, the so-called Barker's, but more properly, Manson's, puerperal malarial fever is usually only an evidence of pus in the Fallopian tube, although he would not deny the existence of a pure type of the disease, such as Dr. Manson, and, later, Dr. Barker, have described as puerperal malarial fever. As to Battey's operation, he has undertaken it but once, and the results were very unsatisfactory in what he thought was a well-selected case.

In the section on Practice of Medicine papers by Drs. William H. Bramlett, of Pulaski City; William R. Cushing, of Dublin; P. B. Green, of Wytheville; William W. Parker, of Richmond, and others were read by title.

DR. LANDON CARTER GRAY read a paper on

VERTIGO,

in which, after detailing the various forms of vertigo from organic disease of the nervous system, he spoke at length of the vertigo to which Murchison gave the name of lithæmic. He stated that he has reached the conclusion that this is due to imperfect digestion of the nitrogenized or farinaceous articles of diet, and that it should be treated principally by aiding the digestion and by hepatic stimulants.

Dr. Joseph T. Logan, of Atlanta, Ga., was then elected an Honorary Fellow of the Society, and the elected officers were installed.

AFTERNOON SESSION.

DR. GEORGE B. JOHNSTON, of Richmond, described a method of securing

PERMANENT DRAINAGE OF THE MALE BLADDER BY A RETAINED CATHETER INTRODUCED ABOVE THE PUBES.

He adds to Van Buren's trocar and canula a steel guide twice the length of the trocar, over which the outer canula may be easily withdrawn from the bladder and replaced.

DR. JOSEPH PRICE, of Philadelphia, followed with a paper on

THE PRESENT STATUS OF ABDOMINAL SURGERY.

He insisted that it was the duty of the surgeon to prepare himself for the unexpected when he undertakes abdominal operations. Vaginal punctures, he said, are more dangerous than incisions through the abdominal wall. As to ectopic pregnancy an operation should be performed as soon as the condition is discovered. The placenta should be removed, if possible; if not, it should be emptied of blood and the cord tied, after which it may be digested by the peritoneum. Flushing the abdomen with hot water in abdominal section is beneficial if there is a tendency to shock. He does not use antiseptics but depends upon cleanliness. As to treatment after such operations he allows neither food nor drink until the stomach becomes quiet; then gives small quantities of liquid diet—butter-milk being excellent. The patient should be kept in bed at least three weeks after an abdominal section.

DR. EDWIN RICKETTS, of Cincinnati, then read a paper entitled

EARLY EXPLORATORY INCISION AS AN AID TO THE DIAGNOSIS OF SOME SURGICAL DISEASES OF THE ABDOMINAL CAVITY,

in which he said that he had found it difficult in many cases to make a diagnosis previously to incision. To open the abdomen is easy enough, but afterward to do the best thing, and that promptly, bearing in mind that half-completed surgical procedures are rarely excusable, is often difficult. He then briefly reported eleven cases that had come under his observation, in which the diagnosis could not be made without an exploratory incision.

DR. HUNTER MCGUIRE, of Richmond, then reported a number of cases of

DISEASES OF THE BRAIN AND SPINAL CORD FOLLOWING URETHRAL STRICTURE.

He believes that long-existing urethral strictures are often followed by painful and dangerous neuroses.

DR. JOSEPH HOFFMAN, of Philadelphia, then read a paper entitled

THE SALIENT POINTS IN APPENDICITIS—ITS DIAGNOSIS AND TREATMENT.

He pointed out that a purely physiological rotation of the cæcum may excite congestion without the presence of any irritating matter whatever. As to treatment, those surgeons who operate between attacks represent the progressive surgery of the day. In women, it is usually best to cut through the median line, for the chances are that in them the disease will not be found in the vermiform appendix, and through the median incision any other abdominal operation may be performed. He condemned exploratory incisions. In man, the presence of an indurated mass in the right iliac fossa, with pain and

fulness in the region detected by rectal examination, is important. The right leg is also often drawn up.

Dr. M. D. Hoge, Jr., of Richmond, then read a paper on the

MODERN TREATMENT OF EPILEPSY.

Dr. E. M. Magruder, of Charlottesville, reported a

CASE OF REMOVAL OF A LARGE VESICAL CALCULUS (ABOUT 2 × 3 INCHES) THROUGH THE VAGINAL WALL.

EVENING SESSION.

Dr. George Tucker Harrison, of New York, read a paper entitled

REMARKS UPON ANTEFLEXION OF THE UTERUS.

After describing normal changes in the shape and position of the uterus, he stated that pathological anteflexion is simply the stability of the flexion. When metritis attacks an anteflexed uterus the angle of which had been variable up to that time, it becomes fixed. The usual symptoms of anteflexion are dysmenorrhœa and sterility—the dysmenorrhœa being due to associated metritis; and the sterility to the endometritis. If these inflammations be removed before they have caused permanent pathological changes, conception may take place. As to treatment, the peri- and para-metric inflammations should be removed. If the uterus becomes sensitive it should be scarified just before menstruation, and the dysmenorrhœa will be moderated. For the persistent uterine catarrh, after dilating the uterine cavity with aseptic laminaria tents and then by steel dilators, the uterine cavity should be washed out with a solution of carbolic acid. Lately, he has been much pleased with ichthyol, incorporated with lanolin, and applied around the portio vaginalis, as an aid in clearing up old peri- and para-metric adhesions.

Following this paper, Dr. L. Ashton, who is about to remove to Dallas, Texas, was elected an Honorary Fellow. Dr. Ashton has been an influential working member of the Society for many years, a Vice-President, a member of the Medical Examining Board of Virginia, and has contributed a number of papers during his many years of Fellowship. The retiring President, Dr. Oscar Wiley, of Salem, was also elected an Honorary Fellow.

CORRESPONDENCE.

CEPHALHÆMATOMA.

To the Editor of The Medical News,

Sir: In The Medical News of September 6, 1890, Dr. H. A. Kelly, writing of cephalhæmatoma, says: "Few men outside of the ranks of the pure specialists are aware that such a disease as cephalhæmatoma exists. Cases which occur in the practice of the general practitioner are diagnosed and treated by him upon 'general principles.' The information which he possesses upon this subject is fairly comparable to that of a physician practising early in the last century." In The News of September 13th, Dr. Barton C. Hirst says: "A cephalhæmatoma on either parietal bone in a newly-born infant is quite common. There is probably not a general practitioner of any experience in obstetrics who has not become familiar with it."

Now, each of these gentlemen is a teacher in a leading medical college, and an authority in the obstetric art. A general practitioner who has seen and diagnosed cephalhæmatoma from specific knowledge of the condition asks, Which one is more nearly correct? Is the general practitioner of this day as ignorant as the opinion of Dr. Kelly indicates?

In Condie's work on *Diseases of Children*, a well-known text-book of twenty-five years ago, is a full account of this condition, he devoting some six pages to its consideration. In the latest American work on diseases of children — *Keating's Cyclopædia* — Professor Parvin evidently considers one page sufficient.

It is true, however, that in most of the text-books on obstetrics there is little or no mention of the subject.

In Volume III. of *Holmes's Surgery*, Mr. Holmes, writing of sub-aponeurotic extravasations of the scalp, shows the difference between them and cephalhæmatoma, and further says "that the same ridge bounding a small circumscribed collection of fluid is also familiar to surgeons as a frequent symptom in blows on the head, and a frequent cause of mistake to inexperienced observers, who confound these appearances with those of depressed fracture." So even the surgeons seem to be familiar with cephalhæmatoma.

Respectfully,
W. H. Sharp, M.D.

Parkersburg, W. Va.

NEWS ITEMS.

Fire in a Texas Insane Asylum. — On the night of September 18th the Insane Asylum at Austin, Texas, was partly burned. No lives were lost, but the inmates of one of the female wards were asleep at the time, and were with difficulty rescued before the building was destroyed. A laundry was attached to the ward, and it was there that the fire originated.

The Chair of Chemistry in the Chicago College of Physicians and Surgeons.—James A. Lydston, M.D., Ph. G., late chief of the Eye and Ear Department, Pension Bureau, Washington, D. C., has been elected to the Chair of Chemistry of the Chicago College of Physicians and Surgeons.

Honor to Sir Joseph Lister.—The Cameron prize in therapeutics of the Edinburgh University has been awarded to Sir Joseph Lister for his development of the antiseptic system of surgery. Mr. Lister will deliver an address before the University during the approaching session, in which he will sum up the results of his labors in recent years.

Influenza in Germony.—It is said that influenza has broken out again in parts of Germany, and that pneumonia is a very frequent complication.

Experiments on an Executed Criminal.—According to the *Lancet*, some interesting observations were recently made in Paris on the body of a criminal who had been guillotined. The heart continued to beat for more than six minutes, and experiments were performed to determine the independence of ventricular and auricular contrac-

tions. A study of the reaction of the contents of the gastro-intestinal tract was also made.

Hypnotism in Russia.—The medical department of the Russian Ministry of the Interior has decreed that, "considering the evils resulting from a public display of hypnotism, public *séances* of hypnotism and 'magnetism are forbidden," and that the "application of the method for therapeutic purposes is to be permitted only in the presence of several physicians."

First Meeting of the Board of Medical Examiners of New Jersey.—The State Board of Medical Examiners of New Jersey will meet in the Senate Chamber of the Capitol, at Trenton, Thursday, October 9th, at 9 A. M., for the purpose of examining candidates presenting themselves for a licence to practise medicine in New Jersey.

Prizes for Essays on Vivisection.—The American Humane Society offers two prizes, each of $250, for the best essays on the question whether vivisection should be permitted in the interests of humanity, and, if so, with what restrictions. Essays should be sent to George T. Angell, No. 19 Milk Street, Boston, before January 1st.

A Song from the International Congress.—The following was sung at the banquet of the Rhino-laryngological Section of the Tenth International Medical Congress, Berlin, August 6, 1890:[1]

RHINOLOGY.

BY MICHAEL, OF HAMBURG.

For all the ills we now endure
With calm philosophy,
There's only one sure, certain cure—
It's Rhinochirurgy.

Chorus.—The nose must straightway be burned out;
'Twill always cure beyond a doubt.
Tiralalalalalala tiralalalalala.

Whoever through his nose doth speak,
Whosoever's nose is clogged,
Whose breath's asthmatic all the week,
Whose sleep is much befogged;

His nose must straightway be burned out,
I will cure him sure, beyond a doubt, etc.

And he who suffers from migraine,
Whose head is dull alway,
Who feels somewhere some little pain,
Or fev'rish gets from hay,

His nose must straightway be burned out, etc.

The maiden, too, with goitre dread,
Whose heart beats pit-a-pat,
Whose eyes seem starting from her head—
Basedow described all that—

Her nose must straightway be burned out, etc.

Then, when acid chloracetic
Fails, as fails aristol,
Pyoktanin energetic,
Or useless iodol,

The nose must straightway be burned out, etc.

Whoever holds his nose too high,
Or pokes it where he shouldn't,
Or gets it twisted all awry,
And pointing where it wouldn't,

His nose must straightway be burned out, etc.

If bent, or straight, or small, or big,
Or short, or long, or lame,
Or dirty, or of famous rig—
It's all and one the same—

That nose must straightway be burned out, etc.

To woman, now, a thund'ring cheer,
Let ev'ry man ring out!
Who don't join in, or doth appear
Unwillingly to shout,

Let his nose straightway be burned out;
Twill cure him, sure, without a doubt.
Tiralalalalalala tiralalalalala.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM SEPTEMBER 23 TO SEPTEMBER 29, 1890.

TESSON, LOUIS N., *Captain and Assistant Surgeon* (Fort Sidney, Nebraska).—Is granted leave of absence for twenty days, to take effect when his services can be spared by his post commander.—*S. O. 72, Department of the Platte, Omaha, Nebraska*, September 25, 1890.

In view of the abandonment of Fort Crawford, Colorado, to which post he is at present assigned for station, J. S. PHILLIPS, *Captain and Assistant Surgeon*, is relieved from duty at that post, and will, upon the expiration of his present leave of absence, proceed to Fort Logan, Colorado, and report to the commanding officer for duty.—Par. 1, *S. O. 135, Department of the Missouri, St. Louis, Mo.*, September 27, 1890.

In view of the abandonment of Fort Gibson, Indian Territory, to which post he is at present assigned for station, W. O. OWED, JR., *Captain and Assistant Surgeon*, is relieved from duty at that post, and will, upon the expiration of his present leave of absence, proceed to Fort Sill, Indian Territory, and report to the commanding officer for duty.—*S. O. 135, Department of the Missouri, St. Louis, Mo.*, September 27, 1890.

In view of the early abandonment of Fort Elliott, Texas, to which post he is at present assigned for station, J. P. KIMBALL, *Major and Surgeon*, is relieved from duty at that post, and will, upon the expiration of his present sick-leave of absence, proceed to Fort Supply, Indian Territory, and report to the commanding officer for duty.—Par. 2, *S. O. 132, Department of the Missouri*, September 24, 1890.

Under the provisions of General Orders No. 43, *c. s.*, Headquarters of the Army, Adjutant-General's Office, the post of Little Kock Barracks, Arkansas, will be abandoned, to take effect not later than October 1, 1890. PAUL R. BROWN, *Captain and Assistant Surgeon*, will accompany Company "E" to Fort Supply, Indian Territory, and there take station until further orders.—*G. O. 15, Headquarters Department of the Missouri, St. Louis, Mo.*, August 11, 1890.

EWING, C. B., *Captain and Assistant Surgeon.*—Is granted leave of absence for one month, to take effect the 1st proximo.—Par. 5, *S. O. 131, Headquarters Department of the Missouri*, September 22, 1890.

APPEL, AARON H., *Captain and Assistant Surgeon.*—The leave of absence for seven days, granted by the commanding officer Fort D. A. Russell, Wyoming, is extended twenty-three days.—Par. 3, *S. O. 70, Department of the Platte*, September 17, 1890.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL ARTICLES.

THE PREVENTION OF SHOCK DURING AND AFTER OPERATIONS.

BY STEPHEN SMITH, M.D.,

PROFESSOR OF CLINICAL SURGERY IN THE UNIVERSITY OF THE CITY OF NEW YORK.

AT the meeting of the American Surgical Association at Washington, in 1888, one of the subjects of discussion was the prevention of shock during and after operations. It appears that, notwithstanding the great improvements in the treatment of wounds, the mortality from operations, due to primary and secondary shock, has not diminished, if, indeed, it has not increased. Failure of operations, due to shock, was attributed to prolonged procedures, nausea from the anæsthetics, and to the chilling dressings now applied. In a word, it was stated that pain and bleeding are less frequent; that slow cutting, nausea, exposure, and low temperature are more frequent; that primary shock has diminished, but that secondary shock has increased.

The truth of these statements is a matter of every-day observation. Rapidity of operation was a cardinal feature of the reputation of operators before the days of anæsthetics. The chief concern of the operator was to lessen the period of pain. Every detail of the procedure was carefully arranged with a view to celerity of execution. But it is evident that precision was then sacrificed to rapidity, and many operations failed to attain their ultimate objects owing to imperfections in the management of details. When, however, anæsthetics removed pain as an element in operations, the attention of surgeons was directed to precision in details, and with very happy results. Not only were the immediate and ultimate results of operations greatly improved, but the range of operations was immensely increased. These advantages were gained, however, only at the expense of prolonged anæsthesia, necessitated by the more complicated procedures and by the greater attention to all the steps of the operation. It follows that, notwithstanding the vast improvements in the details of operations, we are still confronted with shock as an even more fatal complication than formerly.

The preventive measures proposed in the discussion at Washington were simply such as every prudent surgeon adopts, viz., wait for reaction; calm the patient by a cheerful word; give stimulants before the anæsthetic; make anæsthesia short; operate as rapidly as practicable; dress quickly; avoid chilling the patient. After the operation apply dry heat; give liquid nourishment, with stimulants and laudanum, by the rectum; inject brandy subcutaneously; by the mouth give aromatic spirit of ammonia, and also black coffee and brandy; secure quiet, a horizontal position, and sleep; assure the patient that all is over and doing well. But in spite of all of these precautions it was alleged that secondary shock is very liable to occur and prove fatal.

Long since, impressed with the dangers of shock in many modern operations, owing to the long continuance of the anæsthesia, the liability to chilling and to depression from the loss of blood, I have been accustomed, where time will permit, to prepare patients for operations by stimulation to the extent of semi-intoxication. The results have been most happy, especially with feeble patients whose condition has rendered the propriety of an operation very doubtful. The course which I pursue is to give the stimulant in hot milk, beginning from *eight to ten* hours before the operation. Such quantities are given, and so frequently, as to secure a state of happy indifference to the operation on the part of the patient. If the operation is to be at three o'clock in the afternoon, I give directions to commence at six or eight o'clock in the morning. I prefer whiskey to brandy, owing to its slow and persistent operation over a much longer period.

If the patient is not accustomed to the habitual use of stimulants I order an ounce of whiskey every two hours in half a pint of hot milk. If at twelve o'clock, or even at ten, sufficient progress has not been made to render it quite certain that semi-intoxication will be secured at the appointed time, I give an ounce of whiskey in milk every hour during the remaining time. When the requisite effect has been obtained the stimulation should be discontinued. In the case of habitual drinkers I have given two ounces every hour. It is important to give the stimulant in hot milk, which will furnish a large supply of easily-digested and readily-assimilated food, in a form most useful to sustain the vital energies during the critical period of a severe operation, or during a necessarily-protracted operation.

The patient thus prepared has suffused eyes, a flushed skin, a slow full pulse, and complete indifference to the operation, though perhaps previously extremely timid. Frequently he jests and sings

when taken to the operating-table. He is warmly covered except on the part to be exposed for the operation. The assistant who administers the anæsthetic is directed to suspend it as frequently as possible. It will be a matter of surprise to anyone who first administers an anæsthetic to a person partially, or quite, intoxicated by the foregoing means, to observe how quickly, and without a struggle, the patient comes fully under its influence, and how small the quantity required. The pulse remains at its normal standard throughout the operation, the breathing is quiet and regular, the skin continues warm and red, and without unusual perspiration.

During the twenty-four to forty-eight hours subsequent to the operation the condition of the patient remains good. The pulse continues full, the skin natural, the respiration undisturbed, and the mental state is that of indifference, or hopefulness. Neither primary nor secondary shock occurs under such circumstances.

To prevent chilling, the patient should not only be protected by warm clothing, but the wound should be douched with hot water containing the disinfectant. The exact temperature of the water is a matter of much importance, as the term "hot" is indefinite and misleading. In the haste of an operation the hand is often employed to determine the temperature of the water. This test varies somewhat with different individuals, as one person will shrink from placing his hand in water at a temperature which another may bear with little inconvenience. I have frequently tested the temperature of water in which an assistant could thrust his hand, though compelled to withdraw it instantly. This temperature does not exceed 150° F., but more often is 145° F. The hand I regard as a sufficiently good test for a temperature of 145° F. to 150° F. Nor should I care to apply water at a higher temperature than 150° F. to the wound. The late Dr. Varick, of Jersey City, who urged the use of hot water, advocated using water "slightly" below the boiling-point on operation wounds. Water at that temperature would, however, be destructive to tissues, for in my experience water at a temperature of 150° F. will destroy living tissues if it is allowed to remain in contact with them. It can be used at this temperature as a douche only—that is, it must be dashed on the wound. When applied to a fresh wound the surface should be rendered of a dull-gray color. The patient is usually instantly aroused by the heat. The best method of applying the water is by pouring from a pitcher, but not continuously; it should rather be dashed into the wound so that it will penetrate every recess. The effect of the hot water is also seen in the arrest of all oozing of blood from the wound, and this arrest of hæmorrhage is permanent, and prevents secondary bleeding. The application of the dressings immediately follows, and as these consist of materials retentive of heat, there can be no chilling of the patient by the dressings.

During the past ten years I have pursued the above method of preventing shock, and in no instance has that complication occurred.

FEMORAL PHLEBITIS IN TYPHOID FEVER.

By S. C. CHEW, M.D.,
PROFESSOR OF THE PRACTICE OF MEDICINE IN THE UNIVERSITY OF MARYLAND, BALTIMORE.

In the following report of cases of femoral phlebitis complicating typhoid fever, the term phlebitis is used in a clinical rather than in a strictly pathological sense. Cruveilhier and other pathologists of his time, as well as later pathologists, regarded the presence of coagula in veins as proof of the existence of phlebitis; but the investigations of Virchow conclusively showed that arterial and venous obstruction may be brought about by embolism and thrombosis independently of inflammatory change in the vessels. In fact, the changes in the walls of the vessels wrought by inflammation, such as roughening and thickening, which were thought to be especially causative of coagula, may, it is known, exist to a very great extent without producing any such obstructions. It is, for example, not uncommon to find the intima of the aorta and other vessels excessively roughened even by extensive calcification, without the occurrence of clotting.

Into the minute pathology of this subject, which is still under discussion and needs much elucidation, I do not now propose to enter. My object is to call attention to a particular form of venous obstruction that occurs as a complication of typhoid fever, and which cannot be regarded as very uncommon, and yet relatively to many other complications of this disease is perhaps infrequent. The seat of the obstruction in the cases referred to is the femoral vein. The thrombus occasioning it is termed *marantic* or *marasmatic*, and in accordance with the meaning of this term it is believed by some to be due to feebleness of the circulation resulting from heart-weakness and consequent retardation of the blood-current. Whether such slowing and enfeebling of the circulation are of themselves sufficient to produce the thrombus, is, I think, at least open to question. What share the accumulation of blood-plaques or hæmatoblasts may have in its production, as they have been shown to have in the case of other thrombi, has not yet been clearly shown.

In The Medical News of September 7, 1889, three cases of femoral phlebitis complicating typhoid fever are reported as occurring in the clinic of Professor J. M. DaCosta. All of the cases were in men between twenty and thirty years of age. In all of

them the phlebitis was first observed in the third week of the disease; in all the affection was in the left leg and thigh; and in all recovery took place. In this report it is mentioned as a curious fact, of which no accurate explanation has yet been given, that as a rule the left leg is the one involved in the trouble. It is further remarked that as nearly all cases recover, the pathology is difficult to get at. But the result is not always as favorable as in Dr. DaCosta's three cases; for Dr. Austin Flint, Sr., mentions a case in which sudden death occurred in typhoid fever from an embolus being detached from the thrombus and occluding the pulmonary artery,[1] and of course the possibility of such a result exists in every case. Liebermeister reports thirty-one cases of this complication with two deaths: and Murchison seventeen cases with three deaths, which, however, he thinks were not attributable to the complicating phlebitis alone.

The course of typhoid fever is indeed traversed by so many "downward slopes to death;" its fatal termination may occur in so many ways—as cardiac failure from high temperature; cardiac failure from muscular degeneration or exhausting diarrhœa; intestinal hæmorrhage; perforation; hypostatic pneumonia; or brain-lesion—that a person may readily die *with* femoral obstruction, and yet not *from* it.

I have said that this complication is absolutely not very uncommon. In addition to the writers already referred to, it is mentioned by Christison, who states that several examples of it occurred in Edinburgh between 1817 and 1820.[2] He remarks that it resembles the phlegmasia dolens of puerperal women, and says that it was first described by Dr. Tweedie, in 1828, as an occasional sequel of continued fever in the London Fever Hospital.

Strümpel speaks of swelling of one of the lower limbs, caused by venous thrombosis due to cardiac weakness, as sometimes occurring during convalescence from typhoid fever, but as happening in other cases too early to be attributable to weakness of the heart, and therefore due to some local specific cause.[3]

Hutchinson refers to it as resulting from heart-weakness, and states that he has seen both femoral veins obstructed at the same time.[4] None of these writers, however, except Professor DaCosta, as above quoted, refers to its special occurrence on the left side.

On the other hand, I have said that in comparison with many other complications of the disease, this one may be regarded as infrequent, and this statement is borne out by the fact that there is no mention of its occurrence in that storehouse of pathological facts, Cruveilhier's *Pathological Anatomy;* in Harley's very elaborate and learned article on typhoid fever in *Reynolds's System of Medicine;* in the lectures of Sir Thomas Watson; in Professor Loomis's *Text-book of Practical Medicine;* in Professor Bartholow's *Treatise on Practice;* nor in the writings of the late Professor George B. Wood.

In a considerable experience with typhoid fever derived from a practice of many years, I have never chanced to meet this complication among the cases which I have attended primarily, but I have witnessed it in four cases which I was called to see in consultation with professional friends, and the case occurring in the practice of each of these individual physicians was, I believe, the only one that he had ever encountered.

Case I.—The first instance of this affection that I saw occurred in a married man about twenty-eight years of age, whom I was asked to visit in consultation by Dr. Charles H. Riley, in December, 1883. This patient, during the second and third weeks of his attack of typhoid fever, had been as near to death from cardiac exhaustion as I have ever known one to be who ultimately recovered. After convalescence was fairly established he was suddenly attacked with pain in his left thigh along the course of the femoral vessels and running down to the leg, which rapidly reached the degree of intense agony. The vein could be felt as a hard, corded line, and the whole limb became swollen and presented the tense and shining appearance that is seen in phlegmasia dolens. As the temperature of the limb, especially in its distal part, was somewhat lowered, it was kept enveloped in cotton-batting, and the pain was controlled as far as possible by hypodermic injections of morphine. In the course of a few days this pain subsided so that the morphine could be omitted. The swelling of the limb gradually lessened, and the case terminated in perfect recovery.

Case II.—This occurred in September, 1884, in the practice of Dr. James Bosley, who requested me to see the patient. The patient was a married man about thirty-five years old, and was in the third week of typhoid fever, when he developed a condition of the left thigh and leg resembling that in Case I., except that the pain, while severe, was of less agonizing intensity. The œdema and the corded condition along the limb were as marked as in Case I. The treatment was the same, and the patient slowly recovered.

Case III.—This case I saw in June, 1888, in Bel Air, Maryland, in consultation with Dr. B. H. Richardson. There were four cases of typhoid fever in the family, three out of the four being of great severity, and one nearly proving fatal from excessive intestinal hæmorrhage. Another one of the three, a girl seventeen years of age, showed very grave symptoms from an early period of the disease. In the fourth week the left thigh and leg became swollen and painful. The pain was much increased by pressure, but was not severe enough to demand

[2] Library of Practical Medicine, vol. i. p. 198.
[3] Text-book, p. 15, American edition.
[4] Pepper's System of Medicine, vol. i. p. 204.

morphine. The cord-like hardness along the femoral vessels was especially marked. The symptoms gradually abated and recovery ultimately took place.

Case IV.—In August, 1888, I saw a fourth case of this kind in consultation with Dr. Tall, of Baltimore. The patient was a young married woman who had nearly passed through a well-marked, but not very severe, attack of typhoid fever, and had entered upon convalescence, when the same symptoms as those described in the preceding cases occurred in the left thigh and leg. The pain in this case was not violent, but the swelling of the limb and the hardness along the course of the vessels were very great. The subsidence of the symptoms was, however, rapid, no treatment being used except enveloping the limb in cotton-batting.

Four cases of this somewhat unusual complication of typhoid fever have now been described, two being male and two female subjects, so that as far as this number of cases indicates, no sexual proclivity is shown. In all, the left lower limb was affected, and all ended in recovery.

Whether there is any special anatomical explanation of the selection of the left limb I am unable to say. The left common iliac vein is, it is true, somewhat longer and more oblique in its course than the right, but the difference is hardly sufficient to account for the fact that the left femoral vein is so much more frequently affected by a condition from which its fellow altogether escapes.

Again, our Anatomies teach us that in some cases the left common iliac vein, instead of joining the right one in the usual position between the fourth and fifth lumbar vertebræ, ascends on the left side of the aorta as high as the kidney, where, after receiving the left renal vein, it crosses the aorta to join the right iliac. Whether this unusual length and tortuous course of a vessel having no valves may account for the occurrence of the obstruction in conditions of great weakness of the circulation, such as exists in typhoid fever, is a conjecture that may be hazarded; but the explanation could be established only by finding the unusual course in a post-mortem examination of a case in which the complication had occurred. Opportunities for such examinations are seldom presented, and I know of no record of any having been made. Some more probable reason for the complication may exist, but at present I can only look upon it, as Professor Da Costa does, as a curious fact of which no accurate explanation has been given.

EMPYÆMA, WITH REPORTS OF CASES, INCLUDING A CASE OF DOUBLE EMPYÆMA.

By W. A. BATCHELOR, M.D.,
of Milwaukee, Wis.

The following brief histories of a few cases of empyæma are presented not as examples of any new plan of treatment, but simply as additional experience with what are now probably regarded as the best methods of treating a condition which is interesting alike to the physician and to the surgeon.

The subject is one upon which much has been written, and the attention thus called to it has, no doubt, stimulated a greater accuracy of observation, whereby fewer cases of the disease than formerly are overlooked. The discussions and recorded experience of the last few years have, I believe, also done much to improve the methods of treatment. The changes and improvements which have thus been made are epitomized in the two ideas of simplicity and cleanliness.

At the present time I think it may be laid down as an axiom that the presence of pus in the pleural cavity, be it in child or adult, is an indication for incision and free drainage. Cases undoubtedly do recover without operation by spontaneous absorption, by absorption after one or many aspirations, by rupture into the lung and discharge through a bronchus, or by rupture externally through an intercostal space. But the recovery under these circumstances is slow; the patient becomes emaciated, anæmic, and weak, pleural adhesions may render subsequent expansion of the lung difficult or impossible, or the occasional residual products of spontaneous absorption may form a focus for a renewal of suppuration.

The subject of diagnosis may be briefly referred to. The physical signs of a pleural effusion are well known, and if the effusion is large the signs are unequivocal—absolute dulness with displacement of the mediastinum, a sensation of resistance to the percussing finger, a short, wooden percussion-note, and fulness or bulging of the intercostal spaces. The differential diagnosis between purulent and serous effusions is well stated by Money in his book on children's diseases, as follows: "The signs that tell for empyæma as against serous effusion are emaciation, anæmia, long duration, with sweating, fever, clubbing of the fingers, œdema of the affected side, with extra heat of the skin there and enlargement of the veins." An early diagnosis, however, and a *positive* diagnosis at any time, is best made by means of a hypodermic syringe with a large needle, though even the evidence thus obtained is not always absolutely unimpeachable. In a doubtful case I should advise repeated punctures, and, in children that are not easily controlled, puncture under the influence of an anæsthetic. In this sort of exploration let it not be forgotten that skin, needle, syringe, and hands should be *absolutely* clean.

Case I.—Otto O., aged four and one-half years, operated on, June 4, 1888. He had been in my care for the four weeks immediately preceding this, for what I considered as left-sided catarrhal pneumonia. He had passed through the acuter stages

of the trouble, the fever had abated, and there were signs of improvement. My visits and examinations had become less frequent. The improvement, however, was slow, some fever, poor appetite, etc., persisting. In the latter part of this period of four weeks, examinations of the chest were not made so frequently as they should have been, and pleurisy had not been thought of. Finally an examination showed that the chest was enlarged, distended, and dull almost to the clavicle. An exploration with a hypodermic needle made the presence of pus positive, and a quart was withdrawn by aspiration. Two days later a pint was drawn off in the same manner. Two days after this an incision was made between the sixth and seventh ribs in the axillary line, two rubber drainage-tubes were inserted, one long, the other short, and the cavity was freely washed with Thiersch's solution. The chest was washed out at each of the five or six subsequent dressings, at intervals of from two to four days. The dressing consisted of a mass of aseptic gauze, rubber tissue, cotton, and bandage. The long tube was gradually shortened. One tube was removed on the nineteenth day after operation, the remaining tube on the twenty-fifth day, after which the wound quickly and completely healed. The patient is now well and has been since the cicatrization of the wound.

Case II.—Mamie S., aged seven years. First seen, May 27, 1889. Diagnosis, pleurisy of left side with circumscribed pneumonia. On June 8th, puncture with a hypodermic needle revealed pus.

Operation, June 11th: Free incision and drainage as in Case I., irrigation of the pleura with iodine water. No irrigation at subsequent dressings. Tube finally removed, July 3d. Recovery was prompt and the patient is now in good health. In this case a diagnosis was made early, and the early operation prevented the accumulation of any large amount of pus. About four ounces were removed at the time of the incision.

Case III.—Mrs. S., aged thirty-six years, was operated upon in November, 1888. Two years before this the patient began to poultice the lower part of the left thorax, on account of pain which had existed in a greater or less degree since an attack of pneumonia some four or five months previously. Very soon a fistula formed, and continued to discharge pus. During this time the patient had been in poor health, and at the time of my first examination, November, 1888, was in a most unfavorable condition; fever constant, though not excessive, 101° to 103° being about the limit; pulse 120 to 135. She was anæmic, and the urine was albuminous. The left thorax was dull to the clavicle, the apex of the heart was at the right of the sternum. The patient had not menstruated for five months, and for some time previously to that menstruation had been irregular and scanty. Digital examination of the womb revealed no marked enlargement or displacement.

The operation was done November 22, 1888, the intention being to remove portions of four or five ribs. After removing sections of two ribs the condition of the patient was such that it was deemed advisable to complete the operation as quickly as possible, and to defer further excision for a secondary operation. Digital examination through the opening thus made revealed a cavity bounded below and anteriorly by the diaphragm and pericardium. The upper boundary could not be reached by the examining finger. A large quantity of pus and thickened masses of fibrin were removed through the opening. The cavity was well irrigated with iodine water, and the operation hastily completed. This case remained under my care for more than a year, the last drainage-tube being removed December 23, 1889, and the wound permanently closing soon after. The condition of the patient remains most excellent up to the date of writing. During all this time the wound was dressed at intervals of from one to three or four days.

An interesting and important event in the history of this case was the discovery, a month or more after the operation, of a tumor in the abdomen. Reviewing her menstrual history, it was feared that an ovarian tumor had appeared to complicate matters. No positive opinion was given, however, and it was soon evident that the patient was pregnant. Seven and a half months after the operation she was delivered, apparently at full term, of a healthy, large male child. The pregnancy was, no doubt, an important factor in the closing of the empyæmic cavity.

After the thorough drainage there was a considerable but slow expansion of the lung. The excision of two ribs permitted some depression of the chest-wall, and the upward pressure of the diaphragm by the pregnant uterus was an element quite as important as the other two in the obliteration of the cavity. The child, her fourth, is now over a year old, and is strong and healthy. The first child was stillborn, the second lived three days, and the third three months.

Case IV.—Erna T., aged ten years, was first seen June 8, 1889. A diagnosis was soon and satisfactorily made of catarrhal bronchitis and left-sided pleurisy. After ten or twelve days an accumulation of fluid was evident. Later, the fever and sweating, and the slight œdema over the left side, suggested pus. An exploratory puncture under chloroform, with permission to operate, if necessary, was advised, but was at first declined. No improvement following, permission was given. On July 3d, the left thoracic cavity was aspirated, and three or four ounces of thick pus were withdrawn. On the following day the cavity was incised and drained. Between the time of the aspiration and the time of operating there seems from the history of the case to have been a rupture through the lung into a bronchus, for there was increased cough and expectoration of what was said to resemble pus. Some pus, I think, was swallowed, for after the incision the flow of pus, though free, was not so great as I had been led from previous physical examination to expect. The opening into a bronchus was proved by the distinct odor of chloroform at the incision. The pleura was not washed out. On

July 24th, one drainage-tube was removed. On July 31st, the remaining tube was found to have been accidentally pushed or drawn out of the wound, and the opening was practically closed. No attempt was made to reopen the wound. On August 1st and 2d there was a marked rise of temperature. On August 3d the temperature was normal, and a good recovery was soon established.

Case V.—This case was one of double empyæma, and is worthy of note chiefly on account of the rarity of this condition, the operation and treatment being similar to those detailed in the cases already described.

Alban P., aged five years, was taken sick on March 21, 1890. He had an ordinary bronchitis, with considerable pain referred to the left side. Effusion was soon manifest on this side, and after puncture with a hypodermic needle the operation of incision with drainage was made, April 14th. At this time examination of the right side revealed slight dulness low down posteriorly, but the respiratory murmur was transmitted, though faintly, through the dull area. This dulness increased in intensity and extent, and the right side was incised, April 29th. No irrigation was used in this case. The fact that thicker pus and fibrous masses were obtained from the right side would seem to indicate that the trouble began in both sides at the same time.

The patient made a most excellent recovery, the first opening being closed on May 16th, and the second four days later.

These are all the cases that have been under my own care. Another may be mentioned as a further illustration of the same simple mode of treatment. The patient was a youth, aged eighteen years, with empyæma of the right side, and was seen by me with Dr. C. H. Lewis. Incision and drainage, as above described, were followed by a satisfactory recovery.

Two other cases are also perhaps worthy of mention. One was that of a child about a year old. There were cough, emaciation, and fever, with dulness over the lower half of the right pulmonary area. An unsatisfactory puncture with a hypodermic needle was made, and two drops of yellowish serum, which may or may not have contained pus, were found in the needle. Puncture under chloroform, and an operation, if then found to be indicated, were advised and declined. The child improved somewhat while taking cod-liver oil, but died suddenly about six weeks later. The other was the case of a little girl, aged about seven years. The symptoms were somewhat obscure, except that pain was prominent. On about the ninth day there was dulness over the lower part of the left chest, somewhat more marked anteriorly. There was doubt as to the cause of the dulness, and the request to settle it by exploration with a hypodermic needle resulted in a change of doctors. The child died about a week later.

TREPHINING AND OPENING THE DURA MATER AS A DIAGNOSTIC MEASURE IN DISEASES OF THE BRAIN—WITH THE REPORT OF A CASE.

By MILES F. PORTER, A.M., M.D.,

Professor of Surgical Anatomy and Clinical Surgery in the Fort Wayne College of Medicine.

The patient was a boy twelve years old. His family history was unimportant. He was active and healthy, except for the usual diseases of children, until May, 1888, when he had a convulsion, followed in twenty-four hours by an attack of mumps. He recovered from this, and had no further trouble until the following September, when he had a second convulsion. He was now placed in my care, and with the use of bromides he averaged about one fit weekly until July, 1889. From this time until the following September he had none. In October of the same year he had two in one day, and after that two each month until January, 1890. From the latter date until March, 1890, they were more frequent. The patient was then taken to another physician, under whose treatment he improved, and from the first week in March until the last of April he had no fits, when, notwithstanding the continuation of the treatment, he grew worse, and was brought again to me on May 1st, when he was having from twenty-five to fifty convulsions every twenty-four hours. I now learned that he had had *la grippe* in April, and that before he had entirely recovered he fell into the water and remained outdoors in his wet clothes for some time. When he reached his home his neck was stiff and the head drawn to the right side. Until May 1st, his attacks were those of ordinary epilepsy, with an aura on the outer side of the right leg and thigh, except that they usually commenced in and were most marked on the right side, and that sometimes when he felt a fit coming on "he would get up and run about for a minute or two, belch considerably," and thus prevent a major attack.

After May 1st, he did not lose consciousness during the attacks, which would commence by flexion of the fingers of the right hand, quickly followed first by tonic then clonic spasm of the right upper and lower extremity, and right side of the face, in the order named.

Paralysis commenced May 1st, involving first the thigh and leg, then the arm, and lastly the face on the right side; motor aphasia developed with the facial paralysis. The paretic symptoms increased until July 2d (the date of operation), at which time he was unable to walk, could not raise his hand to his mouth, sat with his head falling forward and to either the right or left, and with a decided lack of expression in the right side of the face. He spoke with great hesitation and difficulty. There was no ptosis. Though his slowness in replying to questions and lack of facial expression made it appear that his mental faculties were failing, yet I feel certain, from frequent examinations, that they were as active as

[1] Read before the Fort Wayne Academy of Medicine, August 12, 1890.

ever, or nearly so. So far as I could determine, none of the muscles were completely paralyzed, but only in a condition of marked paresis. There was no loss of sensation, and the patellar reflexes were normal. He was given 90 grains daily of bromides, in different combinations, from May 1st until the operation. For the three weeks preceding the operation he also took from 75 to 120 grains of potassium iodide daily.

I should state that in 1884 the boy fell and received a scalp-wound in the left occipital region, but there were not then, nor are there now, any signs of fracture of the skull, nor is there any tenderness in the region of the scar.

The patient was sent to Dr. K. K. Wheelock for an examination of the eyes, but absolutely nothing abnormal was found. During last June his temperature was found on several occasions to be from one to two degrees above normal.

There was no tenderness upon percussion, but there was slight headache, referred to both temporal regions. On three occasions only was any peculiarity of the pupil noticed—dilatation of the right. Having presented the patient to the Fort Wayne Academy of Medicine, and being unable with the aid of the Fellows to arrive at a diagnosis, and in view of the fact that the patient was steadily growing worse, I proposed an exploratory trephining, to which the parents and the patient gladly assented, each remarking that death was preferable to existence in the present condition. It was understood that whatever was revealed by the exploration should be dealt with in whatever manner seemed best. It was explained to the parents that we might find no visible lesion, and that in that case there would yet be a *faint hope* that the operation would be beneficial.

Operation.—The operation was performed, July 2d, in the City Hospital in the presence of Drs. Jelleff and Boyers, of Decatur, and Drs. Dills, Mary Wheery, H. S. Myers, C. Proegler, and Greenawalt. Dr. W. P. Wheery administered the chloroform, while Drs. A. P. Buchman and H. McCullough assisted.

The left Rolandic fissure was located according to the method of Championnière, as described in *Wyeth's Surgery*, the lines on the scalp being marked in ink and a fine bone-drill used to mark the skull after the flap was turned down. A long horseshoe-shaped incision was made, the flap turned down, and two buttons of bone were removed with a seven-eighth-inch trephine, the second being a little below and in front of the first. The intervening bone was removed with a rongeur, thus exposing the dura overlying the ascending parietal and frontal convolutions and a portion of the foot of the third frontal. Nothing abnormal appearing, the dura was divided by a curved incision to the length of the opening in the bone and turned aside. Examination of the areas supposed to be involved, by inspection, palpation, and by the use of a probe and exploring-needle, revealing nothing, the dura was stitched, the flaps were united and dusted with iodoform, and the parts covered with carbolized gauze and a bandage. Silk was used for all the stitches. Strict asepsis was observed and nothing but boiled and strained water was used in cleansing the wound. The dressing was changed at the end of twenty-four hours, as the outer bandage was stained by the oozing. It was not removed again until the seventh day, when the stitches were removed and complete primary union found to have taken place. From the 5th to the 14th of July the patient was under Dr. H. McCullough's care, during my absence from the city, and for his kindness I desire here to offer my thanks.

There was nothing of importance in the convalescence so far as concerns the operation *per se*. The highest temperature—100⅕°, with a pulse of 140—was found on the day following the operation. Contrary to Dr. McCullough's wishes, the patient left the hospital on the tenth day after operation, and since that time has not been confined to bed.

The convulsions steadily decreased up to the sixth day, when the patient had only four; they then increased until the ninth day, when he had eleven; while on the tenth and last day in the hospital he had seven. After he went home they continued to decrease, so that between July 25th and 31st he had but one.[1] With the decrease in number there has also been a decrease in severity, while there is a very marked improvement in his speech, and he walks unassisted, and is able to throw objects to a distance of 100 feet with his previously paralyzed arm and to feed himself with it. His facial expression is likewise improved, he is cheerful, sings, plays, and, in short, enjoys life once more.

Remarks.—I do not wish to be understood as reporting this case as one of epilepsy permanently benefited by operation, nor as one which promises complete recovery. Time alone can decide as to the ultimate results.

Before the operation I was inclined to look upon the case as one of epileptoid convulsions due to organic disease of the cortex or subcortical substance about the Rolandic fissure, and I am still inclined to that opinion. The number and character of the convulsions, of late, and the paresis exclude, it seems to me, the diagnosis of functional epilepsy. Acquired syphilis is out of the question, while the family history and the treatment by the iodides set aside the idea of inherited syphilis. The paresis of only certain groups of muscles, together with the absence of sensory paralysis and eye-symptoms, is against a diagnosis of basal disease. Certainly the clinical history of the case since May 1, 1890, clearly points to the diagnosis of Jacksonian epilepsy due to a lesion of the Rolandic zone, commencing probably in the upper and extending thence to the lower portion. And in view of the normal appearance of the cortex and the absence of tenderness on percussion we may conclude that the sub-

[1] The patient walked to my office, a distance of more than a mile, to say that he had had no convulsions for eight days. His paresis also continues to improve.

cortical substance is the seat of the trouble. In the absence of paralysis we would be less warranted in thus localizing the trouble, for then we might reasonably conclude that the irritation originated at some distance from the seat of explosion.

"But if following these limited spasms paralysis of motion should occur in the parts formerly convulsed . . . . and still more so if a succession of monoplegia should result in a general hemiplegia, then we may with certainty diagnose organic disease of the Rolandic zone of the opposite cerebral hemisphere."[1]

But what shall we say of the attacks prior to May 1st, when, as I have said, they resembled ordinary attacks of *grand mal*, except that the convulsions usually commenced, and were worse, on the right side.

It must also be remembered that while at first the attacks began in the outer side of the knee and thigh, that after May 1st they began with flexion of the fingers. This raises the question as to whether we may not have in this patient a functional epilepsy followed by organic changes, such changes being the result of the epileptic attacks or a complicating disease. I was not able to see the patient in one of the attacks prior to May 1st, but had the symptoms been noted by a trained observer my opinion is that, taken with the history since that time, we would have a well-defined clinical picture of Jacksonian epilepsy.

The most important point connected with this, as well as with all similar cases, has not yet been touched upon. I have concluded—and for the sake of argument will assume that the reader agrees with me—that the trouble is organic and involves the subcortical substance in the Rolandic zone; but, what is the exact nature of the disease?—is it a tumor? and if so, is it fluid or solid? and if solid, is it encapsulated? To decide these and similar questions exploratory trephining is not only warrantable but demanded in many cases, and it is to add my mite to the statistics of this question and to excite a discussion by the Fellows of the Academy that I report this case so soon after the operation. Ferrier, as quoted by Gray in the article previously referred to, says: "In the absence of definite indications as to the character of the tumor . . . . trephining is, in my opinion, justifiable as a diagnostic measure."

I desire to state as my opinion that it is advisable as a diagnostic measure in cases other than those of tumor; for while it may not, as in my case, clear up the diagnosis, it is *per se* an operation attended by very trivial danger considering the gravity of the cases in which it should be resorted to.[2] If the disease proves amenable to operation, we avert death, which is otherwise inevitable; if it cannot be removed by operation, or nothing is found, we have done our duty. Besides, the operation will occasionally, albeit rarely, cure, though nothing further than trephining and exploration be done. How the cure is brought about in such cases no one knows, any more than we know why or how exploratory laparotomy cures tubercular peritonitis, or removal of spinous processes and lamina of vertebra cures spinal paralysis, or dilatation of the cervix uteri cures the vomiting of pregnancy. To my mind the most satisfactory answer to this question is that given by Dercum and White,[1] who say:

"It would seem as though the local shock had been promptly followed by a corresponding reaction, in which the vitality of the tissues had been raised sufficiently high to determine a return to the normal state."

Several other points of interest suggest themselves in connection with this case, but these I will leave until a future time, when I shall report the further progress of the patient. I will conclude with the statement that it is my firm conviction that exploratory operations should occupy the same relation to brain surgery that they do to abdominal surgery.

100 Fairfield Avenue

[2] I mean, of course, when performed with thorough antiseptic precautions.

THE TREATMENT OF HÆMORRHOIDS BY EXCISION.[2]

By CHARLES B. PENROSE, M.D., Ph.D.,
surgeon to the gynecean hospital and to the out-patient department of the pennsylvania hospital.

My object in presenting this paper is to urge the more general use of Whitehead's operation of excision in the treatment of certain cases of hæmorrhoids.

In 1887, Mr. Whitehead, of Manchester, reported[3] three hundred consecutive cases of hæmorrhoids which had been successfully treated by the method of excision and suture. His operation is performed in the following manner:

1. The patient is placed on a table in the lithotomy position, with the hips well elevated.

2. The anal sphincters are then thoroughly paralyzed by digital stretching.

3. The mucous membrane of the rectum is divided at its junction with the skin around the entire circumference of the bowel.

4. The mucous membrane, with the attached hæmorrhoids, is dissected from the submucous tissue, and the cuff or cylinder thus formed is dragged below the margin of the skin.

5. The mucous membrane above the hæmorrhoids is then divided transversely, thus removing

[1] Annals of Surgery, July, 1890.

[2] Read before the Philadelphia County Medical Society, September 10, 1890.

[3] British Medical Journal, February 6, 1887.

the pile-bearing area, and the operation is completed by suturing the upper margin of the severed membrane to the free margin of the skin.

The advantages claimed by Whitehead for this method of treatment are based on pathological and on surgical reasons. He considers that the internal hæmorrhoids, which are generally regarded as localized distinct tumors, amenable to individual treatment, are, as a matter of fact, component parts of a diseased condition of the entire plexus of veins surrounding the lower rectum, each venous radicle being similarly, if not equally, affected by an initial cause, constitutional or mechanical.

The operation of excision is the only one which removes this whole diseased area. It is, therefore, demanded for this pathological reason. It is in addition surgically more perfect than any other method of treatment, because it provides for the readjustment of healthy tissues with the object of securing primary union and rapid convalescence. It does not leave the sluggish ulcer of the cautery, nor is it attended with the pain and slow convalescence of the ligature.

My experience with this operation is limited to ten selected cases. Only those cases were selected in which there existed a complete circle of hæmorrhoidal tumors surrounding the lower margin of the rectum, since for such cases Whitehead's method of excision seems to be particularly adapted.

The details of the operation are simple and easy to execute. In dividing the mucous membrane from the skin it is best to begin at the posterior margin of the anus in order to prevent the blood from obscuring the field of operation. No skin should be sacrificed, even though there appear to be redundant tags around the margin of the anus. The skin always retracts somewhat and the tags shrivel and disappear before firm union has taken place. Failure to observe this rule may result in subsequent serious trouble. Kelsey[1] reports the case of a woman who had been subjected to a so called Whitehead operation and who presented herself to him with a complete circle of excoriated mucous membrane extending for one inch outside the anus. It is probable that in this case the operator had sacrificed too much skin.

On the other hand, the upper section of the mucous membrane should be made in the same horizontal plane throughout, in order to prevent subsequent ectropion ani.

The dissection of the mucous membrane from the underlying tissue is exceedingly easy except in some cases of long-standing piles. The attachment of the submucous tissue is very loose, and separation can be effected with the finger or with the handle of the scalpel. It is not always possible to dissect the piles completely from the underlying structures, as they may involve not only the mucous but the submucous tissues, and in such cases it is necessary to cut partly through the piles until the healthy mucous membrane above is reached. Repeated attacks of inflammation of course render closer the adhesion of the pile-area to the underlying structures. In one of my own cases in which the piles had existed for forty years, and had frequently been inflamed, the adhesions to the two sphincters were so close that a few muscular fibres were cut away during the removal.

The amount of blood lost during the operation is surprisingly small. Whitehead states that he has often operated on severe cases and not found it necessary to twist a single vessel. In five of my cases no hæmostasis was necessary. Bleeding is avoided by adhering closely to the mucous membrane in the dissection, as the larger arterioles lie beneath the submucous tissue. Arterial bleeding occurs in those cases of old piles which have been subjected to previous operation or to attacks of inflammation, and in which dilatation of the rectal and anal arteries has taken place secondary to dilatation of the hæmorrhoidal veins. The bleeding from the upper divided edge of the mucous membrane can be reduced to a minimum by following Whitehead's method of inserting the sutures as each portion is divided, or by adopting Marcy's plan of introducing a circle of shoemaker-stitches of catgut around the mucous membrane above the piles before cutting the mass away.

Whitehead's advice is to remove in all cases the complete cylinder of mucous membrane, whether or not the whole of this area appears to be diseased. He gives this advice for the reason which I have already stated, that he considers the individual piles as but part of a general pathological condition, involving all the lower hæmorrhoidal veins of the rectum.

Whether we accept this pathological view or not, it is best to follow his plan, and to make a complete circular division of the mucous membrane, as by this method the most perfect surgical results are obtained, and ectropion ani prevented. I have seen a case in which only one-half of the circumference of the mucous membrane of the rectum was removed, and a few hours after the operation an œdematous swelling formed in the other half, which has now resulted in a hæmorrhoidal tumor almost as annoying as the one for which the operation was performed.

In attaching the mucous membrane to the skin Whitehead uses interrupted silk sutures. He never removes the sutures, but allows them to ulcerate through—a process which is very easily accomplished. In my own cases I have used the continuous catgut suture.

[1] New York Medical Journal, October 5, 1889.

The treatment of these cases after operation is very simple. It is rarely necessary to use opium or the catheter. An opium and belladonna suppository introduced immediately after the operation is in most cases all that is required. The bowels can be moved in from twenty-four hours to four days, and with very little pain. Absence of pain after Whitehead's operation is due to the thorough paralysis of the sphincters, and to the fact that no source of irritation is left beyond that of a clean linear incision, united without tension and without strangulation of tissue.

A glance at the histories of my own cases shows that they were all cases of aggravated hæmorrhoids, in which the piles covered the whole circumference of the lower part of the rectum. In all the cases the disease had existed for many years, and two had been previously subjected to operation by the ligature.

In only one case was there anything like free bleeding during the operation.

In all the cases a suppository of ½ grain of extract of opium and ½ grain of extract of belladonna was introduced immediately after the operation, and this was all the opium required except in three cases, in which ⅙ grain of morphine was subsequently administered.

The catheter was used in only three cases, and in these for a period not longer than twenty-four hours. The length of time that the case is confined to bed depends to a great degree upon the social standing and the disposition of the patient. In my cases it varied from two to ten days. Every case should be able to sit up in four or five days, and to resume work in ten days or two weeks.

The bowels were opened without pain in from twenty-four hours to four days after operation.

No complications of any kind followed these operations. Union takes place quickly, and generally one dressing, taken off when the bowels are moved, is all that is necessary. In no case was there incontinence from paralysis of the sphincters, or any tendency to stricture from contraction of the scar.

Since the publication of Whitehead's paper his method of operating has been tested by many surgeons. The operation cannot be criticised on surgical grounds, as it is certainly the most perfect plan of treatment, surgically speaking, which has been proposed.

The immediate removal of the tumors, the coaptation of healthy tissues, and primary union, are substituted for slow strangulation by the ligature, or removal by the cautery and healing by granulation.

The applicability, or the necessity, of this operation in all cases of hæmorrhoids, is, however, open to criticism. If we accept Whitehead's views in regard to the pathology of piles, and believe that the whole venous plexus surrounding the anus and the lower end of the rectum is in a pathological condition in every case of hæmorrhoids, even though there may be present only one or two isolated tumors, then, of course, the complete removal of this area is indicated.

But that this view is not true is proved by the thousands of cases which have been permanently cured by the ligature and the clamp. The method, however, is indicated in all cases of aggravated hæmorrhoids in which the vascular tumors cover the whole or the greater part of the circumference of the bowel. In such cases the operation presents no great difficulties. Statistics show that it is at least as safe as operation by the ligature or the clamp, and it is certainly followed by a more rapid convalescence, and much less pain and discomfort.

PERNICIOUS ANÆMIA, WITH A REPORT OF FIVE CASES.

By A. McPHEDRAN, M.B.,
Lecturer on Clinical Medicine in the University of Toronto, etc.

Each of the following cases possesses features sufficiently interesting for publication. My experience leads me to believe that pernicious anæmia is much more common than is generally supposed, and that, as in other diseases of an obscure nature, a diagnosis is seldom, if ever, made until the case has lasted some time. This has been true in all my own cases, and I have seen nothing in the reports of cases which would lead me to believe that my experience differs from that of others. It would be very interesting to know the effects of treatment begun in the early stage.

Case I.—B. T. P., aged forty-nine years, a physician practising in the northern part of Canada, came under the joint observation of Dr. Byron Field, of Toronto, and myself, on May 1, 1889. His family history contained nothing of moment. He had been subject to "bilious" attacks occasionally for several years; his health was otherwise good until three or four years ago, when he noticed that he was less vigorous, and that his "bilious" attacks were more frequent. He gradually became anæmic, but this did not attract particular attention till the autumn of 1888, when anæmia was quite decided. He continued to attend to his laborious practice, though with increasing difficulty. Toward the end of the winter of 1888–89 he found it almost impossible to continue his work, but he persevered until he was compelled to give it up—about April 15th. He had been under treatment for some time for anæmia, taking iron and digitalis freely but without benefit.

After giving up work he grew rapidly worse, and on the evening of May 1, 1889, when first seen by

Dr. John Ferguson, Dr. Field, and myself, he was in a state of marked delirium, from which he could be recalled to only a semi-conscious condition. He had just passed through an extremely severe chill; his temperature was 104° F., pulse 120, small and weak. The body was well nourished, but there was extreme pallor with a decided lemon color. Vomiting troublesome; the stomach was distended with gas, much being belched up; and there were frequent loose motions with considerable flatus and colicky pains. The heart and lungs presented nothing abnormal; the liver and spleen did not seem to be enlarged.

On the next day the blood was examined; it had a venous tinge and appeared diluted. The corpuscles showed no tendency to form rouleaux; they varied greatly in size and shape, measuring from three to twelve μ. Of the large ones the greater number were irregular in shape, being oval, pear-shaped, balloon-shaped, and pointed. Some seemed to be budding, the bud being from one-fifth to one-third the size of the corpuscle. All the corpuscles were pale, but some were decidedly paler than others. There was also some granular débris, rather dark in color. In estimating the number of corpuscles Gowers's hæmacytometer was used. There were 745,000 per c.mm.—an average of 100 squares. No increase in the number of white corpuscles. Not having the appliances the percentage of hæmoglobin was not estimated, but it was very low, though probably relatively higher than the corpuscles. The patient was given champagne at short intervals until the stomach became quiet; then a pill of arsenious acid, $\frac{1}{40}$ grain, every three hours, the interval to be shortened to two hours after a few doses. Diet: milk, raw or peptonized, matzoon, beef peptonoids, etc.

May 3. Another chill; temperature 104°; enemata of milk and whiskey given.

4th. He was more rational; had a slight hæmorrhage from the mucous membrane of the mouth and spat a few clots. He retained medicines and nourishment, but was extremely restless and obtained only short periods of sleep; diarrhœa troublesome. The urine had to be drawn by a catheter. It was high-colored, specific gravity 1010, acid, no albumin. Not examined with the microscope. The arsenic was given every two hours, except during sleep. He received ten doses ($\frac{1}{4}$ grain) in twenty-four hours.

6th and 7th. Polyuria—about 100 ounces of urine being passed daily, which was acid, and darker than such dilute urine should be; specific gravity 1005. Great thirst and restlessness.

8th. A severe chill lasting fifty minutes at 1 A. M. Temperature during chill 104°. Very restless and delirious. Often refused food. Temperature had fallen to normal at 5 A. M.

10th. His appearance was better. Dr. R. A. Reeve examined the eyes and found the fundus very pallid and containing many small hæmorrhages. There was a large hæmorrhage into the conjunctiva of the right eye. The blood on being drawn looked like cherry-juice. Corpuscles were more regular in shape and seemed higher colored; less débris; 731,746 per c.mm. Some tendency to form rouleaux. Bowels regular. Urine paler and in considerable excess.

20th. Progress slow; greatly troubled with flatulence. Consciousness gradually returned. Has taken increasing amounts of nourishment, and with relish. A hasty examination of the blood showed about 1,000,000 red corpuscles per c.mm.; corpuscles much more regular in shape; no débris; fewer microcytes. Arsenious acid, $\frac{1}{4}$ grain daily.

25th. Greatly improved in appearance; a decidedly pink tinge to lips and finger-nails. A few days before this the veins on the back of the hands were of a peculiar magenta color. His appetite was good and had to be restrained. As more convenient, the arsenic was given every three hours and liquor arsenicalis substituted for arsenious acid, from thirty to forty minims being taken daily without any gastric disturbance being caused. Some sores in the mouth healed rapidly after applications of nitrate of silver.

30th. Able to take a full diet. Corpuscles showed more tendency to form rouleaux, and were more regular in shape, but still varied in size; 1,676,687 per c.mm., the average of 80 squares.

June 7. Color greatly improved; able to sit but not to walk. Corpuscles 2,300,000 per c.mm., quite regular and scarcely distinguishable from normal.

11th. The fundus oculi still pallid, arteries small but otherwise normal.

18th. Corpuscles 2,500,000 per c.mm.

July 1. Corpuscles 3,217,000 per c.mm.; rouleaux fairly formed; a few irregular corpuscles found; diameter varied from 6.6 to 10 μ. Felt well; appetite and digestion good; bowels regular. He slept well, and was able to walk a mile. Still taking 30 minims of liquor arsenicalis daily. A few days after this he went home.

About July 15th, a copious purpuric rash appeared on the feet, legs, and body, with severe pain and some swelling of the feet, which were relieved by rest and elevation. He said that he had had wandering pains in various parts of the body for four or five weeks before this acute attack. He stopped taking the arsenic and these symptoms soon improved. The rash lasted ten days, but the pains disappeared slowly, and even now pain in the feet troubles him somewhat. It is possible that the rash was due to the arsenic, as a few cases are on record of such a rash from the medicinal use of the drug.[1] The pain and tenderness of the feet may have been due to neuritis caused by the arsenic, but this is very improbable, as such a result is all but unknown. More probably the pains were rheumatic.

July 27. Corpuscles 4,500,000 per c.mm., normal in size and shape; rouleaux well formed.

November 6. Looked and felt well. Able to attend to a fair amount of professional work without becoming tired. General health better than it had been for three or four years. Some disagreeable numbness in feet and a little in hands. Urine normal. Corpuscles 4,100,000 per c.mm., by a hasty estimate.

Since then he has continued well and is attending

[1] Duhring, Diseases of the Skin.

to his practice as usual. He writes me that he feels in better health than he has for several years.

Case II.—The notes of this case are from my hospital case-book, and were taken by Dr. R. W. Palmer, my clinical clerk.

W. J. H., aged thirty-nine years; born in the United States; family history good; a piano-tuner. A small man, not robust, and with a fastidious appetite. Temperate in the use of alcohol, but smoked excessively for some years. His health was fair until 1885, when he had troublesome diarrhœa for some months, and he has not been very well since then. In the winter of 1888, he said, he had pleurisy and pneumonia, and while recuperating from this in the following June, his attention was first called to his extremely anæmic appearance. His complexion had been high-colored. He was in the Toronto General Hospital during most of the winter without improving. He went out in February and returned in May, 1889, after which he was unable to leave his bed. He was extremely anæmic, with a decided greenish-yellow or lemon tint. Conjunctivæ pearly. He was of spare habit but not emaciated. The skin was moist. Temperature, A. M. 99°; P. M. 99.8° F.; pulse 100, fairly full but soft. Heart and lungs normal; soft murmurs at base of the neck. Liver normal; spleen slightly enlarged. Bowels irregular and diarrhœa frequent. Urine high-colored, normal in quantity, acid, specific gravity 1017. No albumin or sugar, but some uric acid crystals. Night-sweats troublesome. Blood-corpuscles 606,000 per c.mm., the average of sixty squares of Gowers's hæmacytometer. No rouleaux formed, many corpuscles were oval, tailed, budding, and pointed. Their size varied from three to eleven μ. Liquor arsenicalis was given, at first 3 minims three times a day, and later 5 minims every three hours. But he soon complained of epigastric pain and diarrhœa, and the abdomen became distended so that the arsenic had to be withdrawn until these symptoms abated. It was then given again, but in three or four days the pain returned and the arsenic was again intermitted. Fearing that he magnified his suffering, an arsenical pill ($\frac{1}{40}$ grain) was ordered under the name of "pil. anæmiæ," that he might not know he was taking arsenic. The pills were given three times a day at first, increasing to six daily, by which time the pain became unbearable. The pills were omitted until the symptoms abated, when they were again taken, to be omitted when the pain became troublesome.

In this manner the treatment was kept up until he left the hospital for the Convalescent Home. At the same time the most nourishing food he could take was given to him, reliance being placed chiefly on milk and nitrogenous foods. The blood was examined from time to time and found to improve gradually, the improvement in the character of the corpuscles being much more rapid than the increase in their number. The temperature remained about normal, occasionally rising to 100°; at such times his urine was darker and he was feeling worse.

June 1. Corpuscles 606,000 per c.mm.
July 3. Corpuscles 1,043.000 per c.mm.
18th. Corpuscles 1,560,000 per c.mm.
August 9. Corpuscles 1,810,000 per c.mm.
16th. Corpuscles 1,620,000 per c.mm.
25th. Corpuscles 1,950,000 per c.mm.
September 4. Corpuscles 2,180,000 per c.mm.; much more nearly normal in shape; tendency to form rouleaux.
16th. Corpuscles 2,520,000 per c.mm.
October 8. Corpuscles 2,600,000 per c.mm.; only an occasional irregular corpuscle; a few microcytes; rouleaux better formed.

He was then removed to the Convalescent Home, a supply of medicine being given him, with directions to omit it when the pains became troublesome and to resume it again when they disappeared. The matron of the Home was so much alarmed at the pain produced that she refused to allow him to remain if he continued to take the medicine. He called to tell me this on October 19th. He was then apparently greatly improved. Corpuscles 2,780,000 per c.mm.; very little irregularity; rouleaux well formed; the color of the corpuscles uniform and not so dark as in June. He was directed to omit all medicines.

November 6. Corpuscles 3,250,000 per c.mm.; no abnormal ones seen. Looked and felt well. Walked a great deal.

December 24. Corpuscles 4,560,000 per c.mm.; normal. Did not remember having ever felt so well, looked perfectly healthy, and weighed 130 pounds—five pounds more than his ordinary weight. Had taken no medicine since leaving the hospital in October.

When last seen, this summer, he was in excellent health and without any trace of his illness. There has not been an opportunity since December to examine the blood.

Case III.—This case I had the privilege of seeing with Dr. George Acheson, of Toronto.

Mrs. M., young, of healthy parentage, gave birth to her second child in January, 1889. She passed through the puerperal period satisfactorily, except that she was rather pale and did not regain her strength readily. Lactation was well established. The pallor progressively increased, and there were recurrent attacks of diarrhœa. She was given iron in various forms without benefit. Some febrile movement was discovered in February and sepsis was feared, but nothing could be found to account for the fever which was not marked or constant. The increase in the anæmic condition was gradual, and pernicious anæmia was not thought of as a possibility until March 1st, by which time a lemon tint of the skin had developed—this tint never became very marked. The urine had been high-colored, of normal volume, and low specific gravity. The blood was found to contain only 1,781,000 red corpuscles per c.mm; their size varying up to 13 μ. No rouleaux were formed, and there was decided irregularity in the shape of the corpuscles. There was also a considerable number of Eichhorst's corpuscles present. The eyes were examined by Dr. R. A. Reeve, and two hæmorrhagic patches found in one eye and three in the other.

Calomel was given to empty the bowels of any offending matter, and naphthalin to keep them disinfected as far as possible. Liquor arsenicalis,

from 10 to 20 minims daily, was given as the stomach would bear it. At the same time the patient was allowed to drink freely of a chalybeate water and red wine.

There was but little improvement in the condition of the blood during March. The temperature gradually fell to normal. She then began to improve slowly, with occasional slight relapses, and by the end of five or six months she had regained her usual health.

The condition of the house not being above suspicion, an examination was made. Under the cellar floor the ground was found covered with stable manure, placed there by the workmen while building. This was decomposing and giving out a very unpleasant odor. There is little doubt that this had much to do with the patient's illness, as other persons in the house became more or less indisposed also. The conditions following parturition rendered her more susceptible, and caused the poison to affect her in the manner described. Whatever the explanation may be, she presented all the phenomena of a decided case of pernicious anæmia, and we must consider it as such until fuller knowledge of the pathology of that disease enables us to exclude everything not belonging to it, no matter how close the resemblance. Should the now rather prevalent opinion that pernicious anæmia is due to a special poison gaining access to the system through an unhealthy gastro-intestinal tract prove correct, then it will be easy to see the connection between that unsanitary cellar and Mrs. M.'s illness.

Case IV.—Dr. A. T. C., a highly-esteemed physician of Toronto. His history is briefly as follows: He had an attack of *la grippe* in January, 1890, and was confined to his house for three weeks. Though far from well, he attended to his professional duties during February. He had a second attack of *la grippe*, in March, and has been quite ill since then. Marked anæmia followed this second attack. At one time malignant disease was suspected, as vomiting, almost at once after food was taken, was a prominent symptom. There were some evidences of Bright's disease, and still are. In April he went to Long Island for the change of climate. He returned in June slightly improved, and since then has been sometimes better, sometimes worse. His temperature is often slightly elevated, at times 101° F. His color occasionally has a decided lemon tint, but usually only slightly so. Though he has lost flesh he is not emaciated. He is subject to attacks of diarrhœa at short intervals, and irregular vomiting.

The blood was examined in June by Dr. John Carden, who found about 1,800,000 corpuscles per c.mm. with very marked poikilocytosis. On July 31st I found the number of corpuscles to be 1,750,000 per c.mm. very irregular, no rouleaux, size from 3 to 13 μ. No increase of white corpuscles. Some reddish-yellow granular debris. The urine was dark, and required dilution by about an equal volume of water to reduce it to normal color; specific gravity 1017: decidedly acid in reaction, and contained about one-sixth volume of albumin. Numerous granular casts, some large and irregular, and most of them containing a large amount of dark granular pigment. Few renal cells, much granular debris of yellowish color.

August 12. Corpuscles, 1,780,000 per c.mm. They appeared less irregular and of better color. The patient felt and looked much better, his appetite improved, bowels were regular, urine much paler, specific gravity 1018. A trace of albumin and a few casts were found, but no yellowish pigment. He always feels worse when he has diarrhœa, and the urine becomes of a higher color. The mouth becomes sore, and the excoriations of the anus—always present—increase. He has been taking no arsenic for some time.

15th. Has had what he calls a "bilious attack"—vomiting and diarrhœa—since yesterday. Took a podophyllin pill, ¼ grain, last night. Ordinarily this would just move the bowels. Urine darker, specific gravity 1018, some pigment-granules and casts; becomes cloudy on heating. He had tried arsenic in solution and pill-form, and found that it always caused disturbance of the stomach and bowels in a few days, with a metallic taste and soreness of the mouth, and increase of the anal affection. It is very doubtful if the arsenic was entirely responsible for these attacks, for he had precisely similar ones such as the attack above described, without arsenic having been taken for days. So much was I impressed with this opinion that I strongly advised him to persevere with the arsenic, notwithstanding the discomfort caused, omitting it when these attacks showed their first symptoms, and returning to it again as soon as they passed off. The ultimate success after long perseverance in Case II. amply justified such advice. He was also advised to try minute doses of corrosive sublimate at short intervals for its antiseptic and tonic effect. He has been at the seaside for a month and has now begun to improve.

Case V.—Elizabeth H., aged twenty-eight years. Married. Family history unimportant. She has not enjoyed very good health since she began to menstruate, at the age of twelve years. She entered the Toronto General Hospital, September 1, 1890, and gives the following history of her present illness:

Two years ago she first noticed a slight greenish-yellow hue to the complexion; she was then in indifferent health. From January until April, 1889, she was quite ill, suffering as she is now, the jaundiced hue being then marked. Bowels irregular, urine at times very dark, appetite poor, and occasional vomiting. During the summer she regained fair health and was able to do her own work, her complexion becoming much more natural. This state of health continued until last winter, when she had an attack of *la grippe*, and since then has been in poor health, with a return of the jaundiced complexion. She gave birth to a child, her fourth, July 25th. She was very well for three days after labor, when her appetite failed. She got up on the tenth day, but had to return to bed and has not been able to be up since. She has had irregular diarrhœa all summer, alternating with constipation lasting for a few days. She usually vomited every morning. Appetite various, at times craving, and at others no desire for food. She is a spare woman, but not

emaciated, very pallid, and with well-marked lemon tint; conjunctivæ pearly.

Physical examination revealed nothing except a slightly enlarged spleen. Heart normal; pulse 100, and very small. Temperature has varied from 100° to normal since her entrance into the hospital, showing no regular gradations. No chills. Urine high-colored, specific gravity 1020 to 1025, some flocculent deposit; no casts or granular matter; no albumin or sugar, reaction acid. About 1,200,000 red corpuscles per c.mm, not very irregular in shape. They varied in size from about 4 to 13½ μ. No increase in white corpuscles.

The treatment consisted in the administration of beta-naphthol, 5 grains three times a day, to disinfect the bowels as far as possible, and liquor arsenicalis 30 minims daily in divided doses every three hours. The diet was milk, yolks of eggs, etc.

The results in the first three of these cases are eminently satisfactory. All the cases present to a greater or less degree the typical features of pernicious anæmia, namely, the marked pallor with the lemon tint and without emaciation; the febrile disturbance; the high-colored, acid urine of low specific gravity, but not increased in amount; the disturbance of the digestive tract as shown by the occasional vomiting and irregular diarrhœa; and lastly, the typical blood-changes.

In all, the pallor was very marked, as was also the lemon tint, except in Case III., in which it was only slight.

Except during the attack of polyuria in Case I., the urine in all the cases was characterized by a high color and low specific gravity, especially during the paroxysms in Cases I., II., and IV. In Case IV. the only one except Case V. in which a microscopical examination of the urine was made, renal casts infiltrated with many granules, were found, and after an exacerbation of symptoms, when the urine was much darker in color, many spherical yellow granules, usually in masses, were found in every specimen. When the exacerbation passed off and the patient improved, the urine became more nearly normal in color, and the granules were not present. Hunter, Mott, and others attach great importance to the presence of these signs in the urine, and think that the phenomena are sufficient of themselves to establish the diagnosis of pernicious anæmia.[1] They indicate a great destruction of red blood-corpuscles with liberation of hæmoglobin, and that the blood-destruction occurs in the portal circulation, as shown by the condition of the liver and the absence of hæmoglobinuria.

These cases agree also in the constancy with which they present disturbances of the digestive tract, the intestine being more severely affected than the stomach. The recovery of the first three cases proves the absence of any serious organic disease—the symptoms point rather to a mild catarrhal condition of the mucous membranes.

Another feature worthy of note is that commencing improvement was characterized by a better shape and color of the red corpuscles rather than an increase in their number. This was true at least in Cases I. and II.; in Case III. no note was made on this point, and in Case IV., in the few observations made, the corpuscles were found more regular in shape during the period of improvement than during the exacerbation. It would seem that the corpuscles damaged during the exacerbation had been completely destroyed, and that the new corpuscles were affected to a less degree by the destructive agent which is probably thrown into the blood during the exacerbation. The absence of marked irregularity of the corpuscles in Case V. is to be noted. It is not exceptional to meet with cases of pernicious anæmia in which, though the corpuscles are very large, the poikilocytosis is not marked.

Pernicious anæmia is characterized by no constant anatomical lesions, though lesions are, however, exceedingly numerous and of great variety. The most constant are those of the digestive tract, and so frequent are these that they have been considered by some as the essential lesions of the disease. In the gastro-intestinal tract have been found malignant disease, atrophy of the peptic glands, inflammatory thickening of the interstitial tissue of the gastric mucosa, and degeneration of the nervous structures of the intestinal walls. In a few, intestinal worms —ankylostoma duodenale and bothriocephalus latus —or a foreign body, as a nail, have been present and their removal followed by recovery. None of these, however important they may be in individual cases, can be regarded as the essential cause of the disease. They exist in many cases without the development of any of the phenomena of pernicious anæmia, while they are absent in other cases of the disease.

Of the anatomical changes resulting from pernicious anæmia, the most important, next to those occurring in the blood itself, indicating as they do the nature of the disease, are found in the liver and kidneys. The hepatic cells in the periphery of the lobules are deeply infiltrated with granules of free iron. Similar granules are found in the epithelium of the convoluted tubules of the kidney. Mott found an abundance of this iron pigment in the small branches of the hepatic vein also, but none in either the intestinal or hepatic branches of the portal vein.[1]

These changes in the liver and kidneys, together with the brownish-yellow "droplets" of hæmoglobin occurring in the high-colored urine, indicate that pernicious anæmia is characterized by excessive

[1] The Practitioner, December, 1889.

[1] The Practitioner, August, 1890.

destruction of blood, which is more or less paroxysmal, and occurs in the portal circulation, with the liberation of hæmoglobin. The hæmoglobin is carried to the liver, where it is decomposed into bile-pigment and free iron, the latter being deposited in the hepatic cells, and, when too abundant for the liver to dispose of, in the renal epithelium, the former being largely excreted as normal or pathological urinary pigments.[1]

The question now arises, What is the morbific agent that causes this blood-destruction in the portal system? In a recent paper[2] Dr. William Hunter, of Cambridge, than whom probably none has done more to elucidate the pathology of this obscure disease, as the result of a careful investigation of a case ending fatally, has, he believes, shown that there were greatly increased putrefactive changes occurring in the intestinal tract, as proved by the increased excretion of aromatic sulphates in the urine. He also succeeded in isolating a ptomaïne that he had not hitherto found in connection with ordinary putrefaction. As ptomaïnes are formed from proteids by the agency of bacteria, and not from ordinary tissue-metabolism, he thinks that this ptomaïne may signify the presence in the intestinal canal of a specific microörganism. In the light of his studies he ventures the following conclusion:

"The special factor required to initiate the symptoms peculiar to pernicious anæmia is the presence, under certain favorable conditions, of organisms of specific nature within the gastro-intestinal tract.

"These conditions may be either local and permanent —malignant disease, various forms and degrees of gastritis, with atrophy of gastric glands; or general and removable—a specially unhealthy condition of the mucous membrane of the stomach and intestine, induced by the presence of intestinal parasites, or by prolonged bad nourishment."[3]

This is a very fascinating theory, and one cannot but wish that it would stand the test of future investigation, but as yet it is "not proven."

Delépine, as the result of a careful study, shows that the liver has, what he suggests might be called a "*ferrogenic*" function, by which he means that it "separates iron from effete iron-containing pigment, stores it in the form of a loose compound, and gradually elaborates it into a more stable albuminous compound, analogous, if not identical, with hæmoglobin, ready for assimilation by the young red blood-corpuscles."[4]

Mott,[5] as the result of a study of three cases of pernicious anæmia, and in the light of the observations of Delépine, suggests that the disease is an exaggeration of a normal physiological process, due to the presence of some abnormal product. Peptone, he says, if not changed, has a marked influence upon the blood, and might lead to such disturbance of this "ferrogenic" function of the liver as to cause increased hæmolysis. In connection with Hunter's theory of a chemical product of the growth of some microörganism, Mott observes that he did not *always* find a relation between the pyrexia, the diminution of the corpuscles, and the color of the urine. In my own cases, as far as my observations extended, this relationship was very marked, and especially so in Case IV.

From all these observations it seems safe to conclude that pernicious anæmia consists in an excessive hæmolytic process in the portal system, remittent and often progressive in character. As to the active agent in this destructive process there is not so much certainty, but at present it seems probable that a variety of poisons may be capable of producing it. In one case it may be a ptomaïne, in another one of the multitude of albumoses, or both a ptomaïne and an albumose may be present. It is possible that such a variety of poisons may explain the varying results obtained from treatment.

Medicinal Treatment.—With an increasing knowledge of the disease the treatment should become more rational. Since gastro-intestinal derangement is so often associated with the disease, our first efforts should be directed to correcting these disorders as far as possible. In the majority of cases an occasional calomel purge seems to be beneficial. Something should be expected of intestinal antiseptics, of which, probably, the best are thymol, beta-naphthol, naphthalin, and similar compounds. Thymol is, probably, the most powerful, but many patients find it the most difficult to take on account of disturbance of the stomach produced, often with vomiting. Beta-naphthol is more easily borne. Naphthalin, it is said, may cause choroidal hæmorrhages, which may possibly simulate retinal hæmorrhages,[1] so that the eyes should be examined before beginning its administration. Small doses of the perchloride of mercury might prove useful both as an antiseptic and as a tonic.

Arsenic still stands preëminent as the remedy for pernicious anæmia. It has effected a cure in a large number of cases, and when it has failed seldom has recovery been attained. It is characteristic of the majority of cases that they bear large quantities of arsenic without any signs of disturbance. Case I. took a fourth of a grain daily for weeks. Some, however, bear it badly, and others not at all. This, as already pointed out, may be due to the degree of gastric catarrh present. Various theories to explain its action have been advanced. By some its effects have been attributed to local antiseptic properties, a very improbable explanation in view of the small

[5] Ibid.

[1] Kolinski: Arch. de Physiologie, April, 1890.

quantity that suffices for the cure of some cases, unless there is a special poison present over which arsenic has peculiar powers; and if this were true, it should always succeed. Others have attributed good effects to stimulation of blood-formation and metabolism. This would not account for the arrest of the excessive hæmolysis that is going on. A third view is that it affects the blood-corpuscle, enabling hæmoglobin to resist the tendency to be dissolved in the blood-serum—in other words, that it increases the resistive powers of the blood to the morbific agent, if there is such an agent. This view is certainly more in accord with the probable pathology of the disease.

Judging from my own limited experience, I think that the greatest amount of benefit will result from the administration of arsenic in frequently repeated small doses, the maximum quantity that the patient will bear being given. If it cannot be taken for more than a few days it should be intermitted until the symptoms of irritation abate. Some patients bear minute doses, a drop or half a drop of the liquor arsenicalis every hour or two, when larger doses disagree. Its administration should be persevered with, if possible, until there is decided benefit, when it may be intermitted probably without disadvantage. Case II. indicates that in some cases at least arsenic is not necessary after convalescence is well established, and that then nothing more than good food and proper care are needed to complete the cure.

In those cases in which arsenic fails, or is not well borne, iron in some form should be tried, as in a few it has succeeded after arsenic had failed. It is a matter of surprise that iron has proved of so little use in this disease. If Hunter's opinion as to the increased putrefactive processes going on in the intestinal tract be true, iron in large quantities is indicated. It has been well established, especially by Bunge,[1] that the good effects of iron in anæmia are due to its powers of neutralizing the alkaline sulphides resulting from putrefaction in the intestines, converting them into stable iron sulphide, thus preventing the sulphides from destroying the iron in the hæmatogen of the food, from which only, and not in the least from the iron of medicines, the blood derives its iron for the hæmoglobin.

Hydrochloric acid, also, should prove of benefit, as in all these cases there must be a deficiency in the digestive fluids, and the more perfect the digestion the more rapid the absorption and the less the putrefaction. Hydrochloric acid alone is, for this reason, sufficient to cure many cases of ordinary anæmia.

Diet.—Our natural impulse, in view of the profound poverty of the blood, is to give those foods which contain an abundance of nutriment for the blood-corpuscle, such as milk, yolks of eggs, meat, and such vegetable substances as the cereals. Until some other course is definitely proven to be better, it would appear best to follow our natural impulses in this matter. Food should be given in small quantities, and often, so that digestion may be rapid, thus giving less time for decomposition.

As the result of a short experience in his last case Hunter advises a trial of a more or less exclusively farinaceous diet, believing that it may be attended with less blood-destruction.[1] In health a nitrogenous diet causes a much greater destruction of blood than a farinaceous or fatty one. While this should be of very little moment in a disease in which the blood is destroyed by a special poison, yet the improvement resulting from the change of diet leads him to believe a trial of the nitrogenous foods desirable. This would certainly seem worth bearing in mind in the treatment of cases that are not doing well on ordinary diet.

In view of the decided benefit usually resulting from the use of arsenic in this disease, and of the fact that nearly all anæmias are benefited by the administration of the remedy, it seems highly desirable to resort to its use in all persistent anæmic conditions of doubtful character without waiting for a positive diagnosis. If this were done much valuable time would be saved in many cases, and possibly we would have fewer failures to record in the treatment of even pernicious anæmia.

ULCERS OF THE LOWER EXTREMITIES.[2]

By J. A. MACK, M.D.,
of Madison, Wis.

Without attempting to discuss the pathology of ulcers, it may be said that whether resulting from occupation or any other non-specific cause, the venous circulation surrounding them will always be found faulty. The veins before ulceration are overloaded, distended, and tortuous; their valves give way and partial stagnation occurs, with transudation of serum, loaded with excrementitious matter, into the surrounding tissue; swelling results, beginning at the most dependent parts and gradually ascending, accompanied with constant irritation of the skin caused by the attempt to eliminate the effete material with which the serum is surcharged. Then if a rupture of a venous radicle, or if the slightest injury of the integument occurs, an ulcer results; or to relieve the intense itching and burning (both being worse at night), scratching is indulged in

[1] British Medical Journal, vol. ii., 1890.

[2] Read before the Central Wisconsin Medical Society, June, 1890.

until finally a small sore results, which gradually enlarges, growing painful as it increases in size.

The arbitrary varieties of leg-ulcers described in the text-books are somewhat misleading. For instance, it is said that an ulcer may become chronic from the age of the patient, improper treatment, or the character of the tissue involved; and that an ulcer may be indolent and irritable from like causes. Yet the fact is, that they all are both chronic and irritable, and so much depends upon the situation, the treatment, the avocation of the patient, and last but not least, upon the patient's susceptibility to pain, that classification is of little moment. As a rule, these cases are not seen until all home remedies have been indiscriminately tried, consequently there is much nerve-irritation in addition to a constantly-growing sore.

The foul, dirty, at times gangrenous, ill-smelling ulcer, covered with some rancid dressing and a bandage saturated with the discharge, may well be called indolent, and speaks forcibly of its owner's habits. To this class a lecture on personal hygiene never comes amiss, but unless the patient is watched the directions are never carried out.

Another class of ulcers are those with a glazed, hardened base, with thick and sometimes everted edges, that are deep, quite extensive, and accompanied with great swelling of the limb and with some eczema. Patients with these suffer greatly, both mentally and physically, and have usually been under the care of many physicians.

Sex is a factor in the symptomatology, for it matters not where situated, or whether indolent or chronic, these sores in the female can always be classed as irritable.

Having had a large experience with these cases (numbering about two hundred) during the past twelve years, and without a failure in treatment, I have arrived at the following conclusions:

1. That the average leg-ulcer is usually treated too harshly.

2. That the surface of the ulcer is a non-absorbing one.

3. That absolute rest is unnecessary.

4. That the age of the ulcer is of no importance.

5. That if the bodily functions are well performed, and if the patient is in fair health, without specific taint, internal medication is uncalled for.

Of all forms of treatment so far proposed, the rubber bandage and absolute rest are best known. My objections to these are, that where eczema exists it is aggravated; that if not present it is likely to be induced, especially in warm weather; that it is impossible to know just how much pressure each turn of the bandage will make, owing to its natural retraction; and that absolute rest is a hardship, especially if the patient's existence depends on his daily labor.

In my practice the following method has been pursued, and with such good results that I am not likely to change:

Gently douche the ulcer with either warm or cold water, dry the limb by enveloping it in a towel and dress with the following ointment: White-lead in linseed oil (common white paint) and vaseline, equal parts; carmine, a sufficient amount to color slightly. Spread thickly on lint, and apply to the ulcer, being careful that the margins are well covered. Immediately over the ulcer, and upon the dressings place a pad of absorbent cotton; now bandage carefully from the toes to the knee, applying the bandage with moderately firm, even pressure. The bandage that answers the requirements best is made from unstarched bleached muslin, and is two inches wide and from eight to ten yards long. If well applied, it is unnecessary to renew it oftener than every second day. A loose bandage or soaked dressing should be immediately changed. A good rule to follow is to renew the dressings often enough to sustain pressure and to keep the limb comfortable.

Additions may be made to the ointment to meet indications; thus, if the ulcer is sluggish or gangrenous, the addition, for a few days, of ten grains of iodide of lead to each ounce of ointment, acts as a mild stimulant, without escharotic action, and also as a disinfectant.

In applying the bandage let the patient sit on a chair with the limb straight, and the heel supported on another chair.

After healing has taken place a well-fitting elastic stocking should be worn.

MASTOIOITIS INTERNA PURULENTA FOLLOWING ERYSIPELAS.[1]

By J. A. Lippincott, M.D.,
of Pittsburg, Pa.

The following case, especially interesting from an etiological standpoint, presents some additional features which help to make it worthy of being placed on record:

E. S., twenty-eight years old, had always enjoyed excellent health, and had never suffered from any aural affection, his hearing on both sides having been, indeed, exceptionally acute.

He was attacked on March 27, 1890, with erysipelas of the face and scalp, which produced great tumefaction. Ten days later two large abscesses, one below the left eye, and the other above the occiput, were evacuated with a bistoury. The swelling and the discharge of pus gradually subsided during the next four weeks.

One week after the beginning of the attack, without previous pain or special local swelling, and

[1] Read before the American Otological Society, July 1890.

without any symptoms in the throat or nose, pus began to flow from the right ear. His medical attendant, Dr. McCormick, of Greensburgh, an intelligent physician, states that at this time the walls of the external auditory canal were normal, and that the pus obviously came from the middle ear through an opening in the drum-head. About May 15th (the otorrhœa in the meantime continuing) the neighborhood of the ear became swollen, and extremely painful. Under hot poulticing these symptoms yielded in about a week. On June 22d the pain and swelling recurred, and continued until I saw the patient June 29th, when the condition was as follows:

Decided swelling and tenderness over whole mastoid region on the right side. Doubtful fluctuation in upper mastoid region. External auditory canal filled with pus, on removing which, at a point about two-thirds of the length of the canal from the external meatus, was seen a furuncular-looking mass with its base attached to the posterior wall, and large enough to render a view of the tympanic membrane impossible. Pus was seen coming from behind this mass, but apparently very little came from the mass itself. A watch of forty inches hearing-distance was heard when lightly pressed against the ear. Examination of the throat and nares negative. The patient complained of deep-seated pain behind the ear, and he was considerably emaciated.

I advised an operation on the mastoid as the quickest way of securing thorough drainage and consequent relief.

Two days later the patient returned and went to the hospital, where an anæsthetic was administered and the mastoid perforated in the usual way. A small collection of pus was found under the periosteum, at a point about three-fourths of an inch above the meatus externus; but neither there nor at any other place could any trace be found of an opening into the mastoid cells.

On perforating the external wall, which was thin, the cells were found extensively broken down, the cavity thus formed being filled with a greenish, unhealthy-looking pus, which reminded me strongly of the appearance of the pus removed some years ago from an orbital abscess following erysipelas. A warm solution of boric acid, thrown into the opening by means of a syringe, escaped through the auditory canal. The syringe was subsequently used daily, but no pus afterward issued either from the mastoid opening or from the meatus.

All the unpleasant symptoms were promptly terminated by the operation. On the fourth day the protrusion from the posterior wall of the canal had almost disappeared, and the tympanic membrane could be easily examined. A perforation in the centre of the latter, about three mm. in diameter, was seen, from which, by means of the cotton probe, a very minute trace of pus was removed. The hearing on the fifth day had improved so that the watch could be heard at two inches. Patient went home in a week with the suggestion to Dr. McCormick to continue the irrigation, and to keep the wound open as long as might seem necessary.

Erysipelas as a cause of mastoiditis interna must be rare. In the limited period which has elapsed since I saw the case above described, I have not been able to find a report of any other case arising in this way.

The sequence of the pathological phenomena is not without interest, nor, it may be added, without uncertainty. The mastoid disease may have been metastatic in character, and so, in a sense, primary. The history of the case before I saw it, however, perhaps tends to show that the first link in the chain was a painless abscess in the middle ear. Then followed invasion of the mastoid cells, accompanied with violent symptoms, and finally rupture through the posterior wall of the auditory canal, which gave temporary relief. The recurrence of the pain and swelling probably arose from blocking up of the opening in the auditory canal.

CLINICAL MEMORANDUM.

OBSTETRICAL.

Eclampsia Fifteen Days after Labor. Death.—J. H., aged thirty-six years; nervous temperament; had been married for four years when she first became pregnant. In the latter part of gestation she had a mild but persistent diarrhœa, and also œdema of the vulva and lower extremities. The œdema of the vulva was excessive and troublesome, but was relieved by treatment. Labor was normal, with but little hæmorrhage and without nervous manifestation. The patient was anæmic, but improved at once with the use of iron and arsenic. One week after confinement there was some irritation of the stomach, but this was readily controlled. She also complained of headache, which her husband stated she had been subject to for some years. Aphasia manifested itself, and when asked how she felt, she would answer, "I feel—I don't know what." The attendants stated that she occasionally had brief "nervous spells," but these attracted no attention. Temperature slightly elevated; pulse 120.

On the fourteenth day after labor damp clothes were put on her, and a few hours later she complained of severe pain below the knee extending upward to the hip and to the abdomen. Morphine and hot applications gave relief. On the next morning her pulse was 130, temperature nearly normal, appetite fair. At 2 P. M. convulsions began, four or five paroxysms following at short intervals. Inhalation of a small quantity of chloroform and the administration of chloral controlled them. Vaginal irrigation with carbolized water had been used for some days, but thinking the trouble might possibly be caused by reflex irritation from the uterus, I now used an intra-uterine douche. The os was somewhat patulous and discharged a slightly-stained mucus which was not offensive. Rapid respiration and coma followed, with death thirty-six hours after the first convulsion.

C. V. Moore, M.D.

Fairmount, Ind.

MEDICAL PROGRESS.

Euphorine.—Under the name of euphorine, Sansoni (*Therapeutische Monatshefte*, September, 1890) describes the physical and therapeutical properties of a new compound which, chemically, is phenylurethan. It is a white crystalline powder, with a faint aromatic odor and a slight taste suggesting that of cloves. It is sparingly soluble in cold water, readily dissolves in alcohol, and is best administered in white wine, in which it is easily dissolved.

Given to healthy men, in doses of from 1½ to 3 grains, euphorine has no apparent effect upon the pulse, the respiration, or the temperature; and in dogs large doses do not lower the blood-pressure, as determined by the manometer. Still more important is the fact that it causes no changes in the blood—in animals the blood remaining normal even after toxic doses have been given.

Clinically, Sansoni finds that euphorine possesses valuable antipyretic, antiseptic, antirheumatic, and, in some cases, analgesic effects. As an antipyretic, he has employed the drug in fever from various causes, such as typhoid fever, croupous pneumonia, phthisis, acute rheumatism, pleurisy, orchitis, influenza, etc., administering it either as a powder or dissolved in wine. The fall of temperature begins within an hour after the administration, reaches its maximum usually in about three hours, and continues, as a rule, for from five to seven hours. In some cases the fall is more brief, and in a few it continues for fourteen hours. The subsequent rise of temperature is usually sudden and accompanied with a chill, the duration and severity of which are proportionate to the intensity of the disease. During the period of apyrexia the patient has a feeling of well-being. Cyanosis is seldom observed, and the pulse and respiration are regular. The antipyretic effect varies in different persons, and it is best to begin with a small dose (1½ grains), increasing until the proper amount is determined. To most adults, from 15 to 22 grains can be given daily without producing harmful effects, its antithermic power being about twice that of antipyrine.

In rheumatism, both acute and chronic, the doses of euphorine should be larger than those given to reduce temperature. From 22 to 30 grains, or even more, should be given daily. In acute rheumatism the good effects appear very soon after the drug has been administered; the temperature falls, and the pain, whether due to inflammation or to the pressure of the swelling, disappears.

As an analgesic, euphorine is very useful in orchitis, less so in sciatica, lightning pains of tabes and trigeminal neuralgia, and is almost useless in intercostal neuralgia and migraine.

The observation that carbolic acid is formed when euphorine is brought in contact with an alkali, led Sansoni to test its antiseptic powers, which, in the case of an obstinate ulcer and one of chronic ophthalmia, he found were excellent.

The Relations of the Cœliac Plexus to Diabetes.—Lustig, in a series of experiments on animals to determine the function of the cœliac plexus, found that extirpation of the plexus, electrical excitation, and irritation by acetic acid produced similar symptoms, namely, glycosuria, usually temporary, but occasionally permanent; acetonuria, which, when of long duration, led to severe symptoms; and subnormal temperature. Further, to determine whether the cœliac plexus is a necessary organ in the production of diabetes, Lustig punctured the diabetic area in the medulla in dogs from which the plexus had been removed. Diabetes resulted from the puncture, showing that the cœliac plexus is not always concerned in the production of the disease.—*Centralblatt f. klinische Medicin*, September 6, 1890.

Pill for the Treatment of Chronic Constipation.—In the treatment of chronic constipation Nothnagel advises the use of the following, when a laxative is necessary:

℞.—Podophyllin . . . . 4½ grains.
Extract of aloe }
Extract of rhubarb } of each . 45 "
Extract of taraxacum, a sufficient quantity.

Mix and divide into forty pills, of which one, two, or three may be taken at bedtime.—*Therapeutische Monatshefte*, September, 1890.

Removal of a Portion of the Liver by an Elastic Ligature.—Terrillon reports a case in which a portion of the liver was removed by means of an elastic ligature. The patient was a woman, fifty-three years old, who for some years had suffered from a painful swelling situated in the right lobe of the liver. An exploratory puncture revealed the presence of a small quantity of fluid resembling that of a hydatid cyst. Although after the puncture the swelling diminished, Terrillon opened the abdomen on the right side by an incision parallel to the false ribs, exposed the tumor, and placed an elastic ligature around it. At the end of seven days the sphacelated portion with the ligature was removed. The wound, of which the base was formed of hepatic tissue, was separated from the peritoneal cavity by firm adhesions. Cicatrization was complete at the end of the sixth week.—*The Medical Press*, September 10, 1890.

The Microbe of Alopecia—Recent researches at the Institut Pasteur have been made by Drs. Vaillard and Vincent in regard to a form of baldness occurring in soldiers, which is very similar to, if not identical with, alopecia areata. Their report, published in the *Annales* of the Institut, show that the malady, in this particular instance, is caused by a micrococcus which, when cultivated and inoculated in lower animals, produces an analogous baldness. Hitherto dermatologists have strongly inclined to the belief that most of the cases of alopecia areata are forms of a tropho-neurosis, no microorganisms with an apparent causative relation having been discovered. The fact, however, that there are on record several cases with histories pointing very directly to contagion, has raised doubts as to the correctness of that explanation.

Massage in the Treatment of Dyspepsia.—Dr. Cséri, of Budapesth, publishes an account of a mechanical plan of treating chronic dyspepsia which he has lately been carrying out with excellent results. The plan consists mainly in suitable dieting, and in a peculiar kind of mas-

sage. The author practises the latter when the stomach is full—about two or three hours after dinner. Frequently changing his mode of proceeding, he strokes and kneads the stomach from the fundus toward the pylorus, first gently and superficially, then more energetically, for ten or fifteen minutes, the patient lying on his back with his legs drawn up, and breathing with his mouth open. During the last few minutes the massage is extended to the bowels. The manipulation is neither painful nor disagreeable, but is very well borne. After the massage the patients experience a feeling of warmth and comfort; occasionally they are sleepy, but the fulness and sensation of weight have generally disappeared. The immediate result of this kind of massage is that the stomach is freed from gas, thus producing a great feeling of relief. The time chosen for the massage is when part of the already chymified ingesta begins to enter the duodenum from the healthy stomach. In dyspepsia the stomach is generally sluggish, and either the quantity or quality of its secretion is impaired, and consequently chymification or peristaltic motion, or both, are insufficient. It is also known that mechanical stimulation of the stomach may increase its secretion, and the author considers himself justified in concluding that massage thus increases the process of digestion. He also finds that at the same time muscular power increases and that the massage mechanically helps to advance the stomachic contents into the duodenum. The rapid cure of pains and general malaise after eating in cases of nervous dyspepsia is easily explained by the fact that the manipulation dilates the pylorus, so that after a few days it offers no impediment to the passage of the food.—*The Lancet*, September 20, 1890.

Toxic Effects of Creolin.—BOREHMEYER reports the case of a child who received a severe contused wound of a finger, which was treated by applications of a solution of creolin (one and one-half per cent.). On the fourth day the finger was covered with vesicles containing a yellowish liquid. On changing the dressing the eruption disappeared, but returned when the creolin was again used.

WACKEY publishes an account of 17 surgical cases dressed with creolin. In 10 union by first intention occurred, but in 7 the creolin produced eczema, erythema, and vesicular eruptions, and desquamation in large patches. At the same time the patients had more or less constitutional disturbance, and an examination of the urine showed that the toxic symptoms were attributable to the presence of phenol. It would seem that children are especially susceptible to the deleterious effects of phenol and its derivatives, and hence are more readily affected by creolin than adults are.—*Therapeutic Gazette*, September, 1890.

Socin's Zinc-paste Dressing.—VON NOORDEN (*Brun's Beiträge z. klinisch. Chirurgie*) has found Socin's zinc-paste an admirable dressing after operations for harelip. The paste is composed of:

Zinc oxide	50 parts.
Zinc chloride	5 to 6 parts.
Water	50 parts.

When exposed to the air it dries very rapidly, forming a firm crust. It should be freshly prepared for use.

After completing a harelip operation, the suture-line and vicinity are disinfected and thoroughly dried, then the paste is spread over the entire upper lip, by means of a brush or spatula, and is reinforced with a very few thin layers of cotton. If the wound extends into the nostril, the dressing should also extend into the opening, but, of course, without blocking it. The nasal secretions will not soften the paste. In from four to six days the dressing may be changed to remove the sutures, and, if not already partly loosened, it can be clipped off. A fresh application is then made, and allowed to remain until it crumbles. The paste has also been used in small wounds of the face and scalp, after herniotomy, extirpation of labial cancer, and even after cœliotomy.—*Annals of Surgery*, September, 1890.

The External Use of Aristol.—POLLAK, of Prague, has had excellent results with the external use of aristol in the treatment of a case of strumous enlargement of the right lobe of the thyroid. He used an ointment prepared as follows:

R.—Aristol	45	grains.
Potassium soap	7½	drachms.
Ether, Alcohol, of each	75	minims.—M.

In a case of epididymitis applications of vaseline containing ten per cent. of aristol also caused a rapid disappearance of the swelling.—*Monatshefte f. Praktische Dermatologie*, September 15, 1890.

Treatment of Eczema and Acne.—According to *Le Semaine Médicale*, September 3, 1890, UNNA recommends the following ointments for the treatment of eczema and acne.

R.—Lanolin	5	drachms.
Liquid chloride of calcium	10	"
Oil of cade	2½	"
Zinc ointment	7	"

This ointment is employed in cases of chronic eczema of a pruriginous form, accompanied by profound infiltration of the skin.

R.—Zinc ointment, Lanolin, Liquid chloride of calcium	2½ drachms.
Precipitated sulphur	45 grains.

The following ointment may be used in cases of acne:

R.—Lanolin, Lard, Liquid chloride of calcium, Oxygen water	2½ drachms.
Precipitated sulphur	1 drachm.

The action of the oxygen water in this last prescription is for the purpose of removing the comedones commonly found in the face of persons suffering from acne. Wherever rapid decoloration of these comedones is desired the following may be used:

R.—Oxygen water	5 to 10	drachms.
Vaseline	5	"
Lanolin	2½	"

SYPHILITIC DISEASE OF THE HEART.

THE power of the syphilitic poison to impress itself upon all the tissues is so well recognized, that *a priori* no objection can be raised to the recognition of a specific cardiac affection due to that virus. If, indeed, the blood be the medium of communication by which the toxic agent—microbe or ptomaïne, or whatever it may be—is diffused throughout the organism, it would seem most natural that the heart itself should suffer in a large proportion of cases. Specific inflammation of the heart-muscle, as well as of the peri- and endo-cardium, and even syphiloma of the heart are sometimes noted in autopsies. No such importance, clinically or pathologically, has yet been attributed to this especial form of syphilitic disease as would have been given it were the heart as vulnerable to this morbid agent as are the mucous membranes, the skin, the bones, the abdominal viscera, the vessels, and the nerves. Indeed, cardiac disease due to syphilis seems to be far less frequently encountered than gross vascular lesions—aneurism, cerebral thrombus, or rupture of weakened vessel-walls.

PROFESSOR ZAKHARINE, of Moscow, according to an extract from his clinical lectures (*Revue Générale de Clinique et de Thérapeutique*, August 20, 1890), believes that the infrequency of cardiac syphilis is not real but apparent, and complains of the want of proper attention to the subject on the part both of clinicians and of pathologists. Especially, he says, have the syphilitic lesions of the cardiac nerves and vessels been neglected. His indictment of the clinicians, moreover, is more severe than that which he brings against the pathologists. "Among the causes of cardiopathies," he says, "syphilis is indeed enumerated—they speak of gummous myocarditis; but on the other hand, not one word is said of the semeiology of syphilis of the heart, so that the perusal of treatises on internal pathology leaves the impression that cardiac syphilis is merely a 'find' of the autopsy, and pertains more to the domain of anatomy than to that of the clinic. One seeks in vain for an answer to the questions, Under what clinical form does syphilis of the heart present itself? How shall it be treated?" The number of personal observations reported toward filling this lacuna in clinical studies is ten.

The acknowledgment is candidly made that, as a rule, syphilis of the heart is characterized by a great complexity of symptoms referable in part to alcoholism, gout, chronic arteritis, gastro-intestinal troubles, and syphilitic lesions of other organs. Moreover, the cardiac symptoms are exceedingly variable, comprising continuous dyspnœa, with palpitation and a sense of oppression, paroxysms of cardiac asthma and of thoracic angina, œdema, and effusion into various cavities. The heart is usually enlarged through hypertrophy of the left ventricle; the pulse is feeble, rapid, and irregular; and frequently there is a systolic murmur.

Now in all this there is nothing at all characteristic, and the further fact is admitted that the diagnosis is to be based upon the antecedents of the patient; whereupon the institution and success of specific treatment—sodium iodide internally, and mercurial inunctions—confirms it. Notwithstanding the success of the treatment, there remain "objective signs of enlargement of the heart, and perhaps a slight systolic murmur beneath the sternum."

There is this to be observed, however, in the report of Zakharine's cases, that the administration of the ordinary cardiac remedies, digitalis and the like, was without influence; while amelioration began with the institution of specific treatment. Furthermore, neither valvular lesions nor alterations of the integrity of the orifices were manifested by objective signs in any instance.

The cases are divided on the basis of their symptomatology into three groups: myopathic, neuro-

pathic, and mixed. Both mercurial inunctions and the internal use of the iodide are considered indispensable in treatment. The inutility of digitalis and its congeners has already been remarked. Two additional therapeutic measures are considered: the institution of a strict milk-diet, and the use of blisters over the præcordium. The milk-diet is recommended because it lessens the gastro-intestinal troubles and increases diuresis, while indirectly, by its diminution of ascites and meteorism, it removes some of the provoking causes of dyspnœa and angina. It is also supposed to diminish the fatty deposit over the heart by causing increased absorption; but no proof is forthcoming in support of this theory. The soothing effect of præcordial blisters, while marked in cases of peripheral neuritis of the thorax, especially angina and intercostal neuralgia in the gouty and rheumatic, is but insignificant in syphilis of the heart.

While this subject is an important one, and we believe that it does deserve more attention than it has received, yet there seem to be two points overlooked by the author. The one, that inquiry is always made by the careful physician into possible syphilitic taint, hereditary or acquired, in the class of cases described, and if it is found, specific treatment is at once instituted—the cardiac complications being assigned, not the prime *rôle* the author would give, but being looked upon as part and parcel of a general infection. Secondly, it is a fact, although not a well-known fact, that sodium iodide and potassium iodide in small doses are extremely useful agents in the treatment of irregularity of cardiac action not due to syphilis.

Furthermore, in our own hospital experience with broken-down, alcoholic, syphilitic subjects, the general nervous, cardiac, vascular, and visceral changes are in general so far advanced that no therapeutic measures can do more than palliate. While, as to diagnosis, if one is willing to ignore the fact that both the whole organism and the organism as a whole are diseased, he can pick out any system he pleases, nervous, circulatory, respiratory, secretory, or any other, to bear the brunt of his nosological discrimination.

LAPAROTOMY THE WRONG WORD.

Although medical science is being continually purged of names which through long usage have been almost sanctioned, there yet remain a number of terms which are so distinctly erroneous as to make a change in their employment necessary. Within the last ten years the term "laparotomy" has come to be employed by the profession whenever it is desired to indicate that entrance has been made by the surgeon to the abdominal cavity through the belly-wall in any of its parts—whether the incision be made about the umbilicus, high up under the diaphragm, low down over the pubis, or, indeed, when it is made over either groin.

Our attention has been called to this point more particularly by an interesting little pamphlet, published by Dr. R. P. Harris, of Philadelphia, who is so well known as a statistical authority upon abdominal operations, particularly those connected with diseases of females. Dr. Harris shows that the term "laparotomy" signifies an incision made into the flank and not into the anterior wall of the body, and suggests that in its place we employ the term "cœliotomy" to designate all operations in which the anterior belly-wall is opened.

Dr. Harris's suggestion as to the employment of this new term is not based upon mere dogmatic name-making, but is sanctioned, as he carefully shows, by the entire history of medicine and by the employment of the word "koilia" by the Greeks.

Every one who has been accustomed to employ medical terms for any length of time, finds it difficult to change the nomenclature to which they have become accustomed, and we fear that it will be a long while before Dr. Harris's scholarly attempt at correction of present errors is fully appreciated and followed. While a multiplication of medical terms is anything but desirable, it is equally necessary that the terms we do use should be correct, and we hope that "cœliotomy" will be employed hereafter by writers upon these subjects, and that laparotomy will be confined to indicate the operation in which the lateral portions of the abdominal cavity are operated upon.

THE EFFECT UPON THE EAR OF PASSING PROJECTILES.

In the August number of the *Archives de Médecine et Pharmacie Militaires*, Surgeon-Major Nimier raises the interesting question of the causation of injuries to the ear by the near approach of flying projectiles, citing several instances of such lesions from the report on the Franco-German war, in three of which the drum-membrane was ruptured and in all more or less impairment of hearing re-

sulted. He gives two possible explanations, the first of which is a modified view of the effect of the "wind of the ball," to which excessive potency used to be ascribed; the other, that the sonorous vibrations are the damaging agency. Without means to decide between the two, he inclines to the latter view, and quotes some of the experimental researches that have been made in gunnery as to the aërial disturbances coming into play under the circumstances. While these furnish some interesting and curious points which make the view to which he inclines possible, it is hard to see how they can do more.

The question principally concerns the military surgeon, for the effect under consideration is too remote and unimportant, in most of its aspects, to interest the gunnery expert, and the amount of experimentation bearing upon it has not been large. Beyond the "blast" region near the muzzle of his gun, the gunner is interested only in the influence of the atmosphere in retarding and deflecting his shot. Yet very interesting studies have been made both in this country and abroad in the photography of the projectile in rapid flight, and it has been found possible to secure pictures of the aërial waves set in motion by its passage. It has thus been shown that a cushion of condensed air is present in front of the shot, that waves stream off both from its pointed head and its sides, and that in the partial vacuum which is left behind it a series of undulations follow which may be visible even to the unaided eye. Probably as the result of this last phenomenon, the point has been noted that a shot moving with a velocity far in excess of the usual speed of sound, carries with it the noise of its discharge, until its flight is retarded to less than 1140 feet a second, when the sound-vibrations moving with their normal speed outstrip it for the remainder of its course. The sonorous vibrations conveyed to the ear by a close-passing shot at high speed are not only those of its own flight, but have the added influence of the discharge. Yet it is too much to believe that these are at all able to cause a rupture of the drum-membrane, much less to knock down and stun a man, as in some of the recorded instances; and it seems "far-fetched" to ascribe the deeper labyrinthine damage to the accompanying sonorous vibrations, rather than to the more palpably potent "wind." To this latter we need not ascribe the power to tear off limbs or effect such gross lesions as were once charged to it; but experiment has shown that it is unquestionably a noteworthy force, quite capable of producing the injuries under consideration.

Probably the same phenomenon occurs near the path of the shot as is at times noted near the gun. The discharge forces the air away from the muzzle in a powerful wave which acts in all directions, though chiefly in the line of fire; but this is followed by a counter-wave of air rushing inward to replace that which has been disturbed. Glass broken by the concussion of heavy guns is not infrequently found to have fallen outward; and there are instances of the same effect when the drum-membrane has been ruptured and a flap turned outward. A passing shot has doubtless both a compressing and a suction effect upon the air in the auditory canal; and the damage is more probably due to the rapid alternation of these two forces than to the direct power of either, although they seem sometimes sufficient to throw a man down.

The persistent impairment of hearing after such an accident is a common result of even slighter injuries, such as a light blow upon the ear. Most aural surgeons have seen instances of permanent tinnitus and lessened hearing which dated from a slap, a shout, or even the kiss of a child upon the ear, and seemed to be due to labyrinthine concussion. Scepticism cannot always find any other cause as probable; and as a kiss has been known to rupture the drum-head (doubtless previously diseased), there is reason to accept the possibility of far-reaching effects from seemingly insignificant and invisible injuries.

Other effects incidentally mentioned by our author, may have no little influence on the function of the ear. He refers to several instances of epileptic seizures and other profound nervous disturbances which have had their origin in the terrific turmoil of battle and have proven both severe and lasting. Aside from the hysterical losses of sensation, there is room for much damage to the organ of hearing under the circumstances; and anyone who has made his recruit's obeisance to the shell which went screaming past him, has doubtless felt that there was a physical shock in the hurtling vibration to which it gave rise even when at a distance. Here the sonorous vibrations alone come into consideration; but it must remain almost impossible to discriminate between their physical and their mental effect, and consecutive impairment of hearing must seem rather a remote and indirect result.

A NEW MEDICAL MAGAZINE.

We have received a copy of Vol. I., No. 1, of *The Journal of the State Medical Society of Arkansas*, which is published at Little Rock, Dr. Lorenzo P. Gibson being its editor.

The journal is well printed, on good paper, and seems to fulfil all that its friends could wish for it, its chief reason for existence being the idea of publishing a medical journal which would represent medical thought in that part of Arkansas, and afford an avenue of publication for the proceedings of its parent, the State Medical Society of Arkansas. We hope it may prove a great success.

REVIEWS.

A Manual and Atlas of Medical Ophthalmoscopy. By W. R. Gowers, M.B., F.R.S., etc. Third edition, revised throughout, with numerous additions and additional illustrations. Edited with the assistance of Marcus Gunn, M.D., F.R.C.S., etc. Philadelphia: P. Blakiston, Son, & Co., 1890.

The second edition of Dr. Gowers's work on Medical Ophthalmoscopy bore the date 1881, since which time so much advance has been made in ophthalmic science that a third revision has been long desired. In the meantime, too, Dr. Gowers had issued his splendid work on nervous diseases, in which he gave evidence that he was well aware of the many pathological relations between the eye and the nervous system, and of the great value of ocular symptoms in the diagnosis of nervous diseases. In this third edition of his Ophthalmoscopy, further proof that the work has undergone a competent and thorough revision is afforded by the appearance of Dr. Gunn's name upon the title-page.

This excellent and almost unique treatise needs no praise, and contains so much of value that minor criticisms will not be construed either as hypercriticism or as detracting in the least from the value of the book as a whole. One may, therefore, the more freely express a regret that so many inelegant and even ungrammatical sentences have been carried over to this edition. Any page will furnish examples. One has frequently to read a sentence several times to detect the exact meaning conveyed by a slovenly and slipshod arrangement of words. For instance, and by no means the worst:

"They always indicate irregularities in the retina in which the vessels lie, commonly swelling, as in retinitis and retinal œdema."

"The aggregations of lymphoid cells which may occur in the nuclear and molecular layers, adjacent to an inflamed disk in tubercular meningitis, have been regarded as such, but their tubercular nature is uncertain."

An instance of revision and not rewriting is afforded by the recommendation, carried from the second edition, to use atropine for dilatation of the pupil, followed by the subsequent and new mention of the preferable agents, homatropine and cocaine. The paragraph in reference to atropine should have been left out, and the use of atropine, simply as a dilator of the pupil, condemned.

A great improvement in the present edition consists in the insertion in the text, and in connection with the subjects to which they refer, of the figures representing the minute anatomy of the tissue under consideration. The cuts themselves have been reproduced by a new process, and are much improved. New illustrations have also been added, and usually they are excellent, though that on page 5 illustrating opaque nerve-fibres conveys a very misleading idea of the more common appearance of this peculiarity.

Under tobacco- and alcohol-amblyopia no mention is made of the possible (or impossible) differential diagnosis of the two, nor of the relative influence of either the alcohol or the tobacco in producing an identical lesion and train of symptoms. Uhthoff's noteworthy work is referred to under the heading of Chronic Alcoholism (wrongly credited to the *Ophtalmic Revue* instead of to *Graefe's Archiv*), but under Tobacco-poisoning it is not mentioned.

Among the substances causing visual disorders should have been included a number of toxic alkaloids, such as mytilotoxin, vanillin, etc.

The appendix contains excellent and much-needed advice upon the methods of sketching the fundus oculi.

The Johns Hopkins Hospital Reports. Report in Gynæcology. 1. By Howard A. Kelly, M.D. Johns Hopkins Press, September, 1890.

This report, the first one which has been published in this branch of medicine by Johns Hopkins University, is typical of the gynæcologist who contributes most of the articles to its pages, showing as it does not only his possession of operative ability, but a wide knowledge of the literature and technique necessary to the successful operator in this branch of medicine.

The pamphlet is illustrated by several very good views of the operating-rooms, and is printed in handsome style in large type.

We congratulate Dr. Kelly upon the contents of the volume, as showing what he has done since he left Philadelphia, and we consider him fortunate in that he has so convenient an opportunity as these reports for the publication of the results of his work.

CORRESPONDENCE.

NEW YORK.

To the Editor of The Medical News,

Sir: This summer has seemed more than usually dull in medical circles, possibly owing to the very large number of physicians who have taken the opportunity to enjoy a European trip, and at the same time attend the International Medical Congress. Besides this, the season has not been marked by the usual amount of sickness, and the absence of long periods of intensely hot weather has had a most beneficent influence on the infants who were trying to fight their way through "the second summer." Of course, there has been plenty of summer diarrhœa, but not much true cholera infantum, thus tending to confirm the opinion held by many students of pædiatrics, that it is long-continued, rather than intense heat, that favors the occurrence of this very fatal malady. Some philanthropists might be disposed to

argue that the improvement in health was due to the labors of the many free physicians, who were sent out under various auspices to look after the health of those who occupy the most crowded and poorest districts of the city; but this, I cannot believe, is an adequate explanation. Medical charity has been dispensed with the same prodigality which in recent years has won for New York an unenviable reputation among the medical profession, and called forth many earnest protests; but those who are best acquainted with the workings of the charities know how feeble is their influence, and how little real progress is made. To preach the gospel of cleanliness in an Italian tenement is to strike terror to the hearts of its occupants, or to heap ridicule upon one's own head; while to insist upon a carefully-regulated diet for a sick infant among the poor Polish Jews means, to them, feeding the baby with lady-fingers and bananas. This season our tenement-house people have not only been supplied with free medicine and medical attendance at their homes, but they have been given beef-tea, milk, infant-foods, and that most costly luxury —ice. They have been taken on numerous day excursions, have been sent to the seashore until their sick children regained their strength, and have even been fed and clothed at the expense of their more fortunate fellow-citizens. All this is most praiseworthy if kept within proper limits, but to the physicians who are brought in actual contact with the beneficiaries of this charity, there is much food for earnest thought. It is exceedingly common for these people to declare solemnly that they have not even a few cents with which to buy the medicine, but it is the rarest to hear any such objection if the physician prescribes whiskey. With all the wealth of medical talent of New York City laid at their feet, it is not surprising that the dwellers in our tenements have learned to select their medical attendants, and they not uncommonly dismiss their family physician who has only a plain "M.D.," in order that they may be treated by Professor ——— of "the College."

The various medical schools have been thoroughly renovated, and each is straining its resources to the utmost to rival its neighbors. The Medical Department of the University is about to celebrate its fiftieth anniversary. During the half century of its existence it has conferred the degree of M.D. upon five thousand eight hundred and thirty-two matriculates. The Faculty have adopted a most commendable measure this year—namely, the requirement of a preliminary examination as a condition of matriculation. The University was the first in New York to adopt the method of clinical teaching by dividing the class into small sections. The College of Physicians and Surgeons has adopted the same plan at the Vanderbilt Clinic, and last year more than one hundred thousand patients furnished the material for this purpose.

The Sloan Maternity Hospital, which is upon the grounds of the College of Physicians and Surgeons, has established a very active obstetric service, about nine hundred deliveries having taken place there in the two and a half years since the hospital was opened. A few years ago, a practical knowledge of obstetrics could be obtained by only a very few medical students; now, in addition to the hospital just mentioned, there has been recently opened for the special purpose of private instruction, an institution known as the "Midwifery Dispensary." It is situated near the populous down-town districts on the east-side, and is managed by several men who have had large experience both in the teaching and practice of obstetrics. A salaried resident physician and a limited number of students who reside at the institution, are always ready to answer calls, and as the cases are attended at their homes, the students have excellent opportunities to learn something of the difficulties that present themselves in private practice, and which are almost unknown in a well-appointed maternity hospital.

CHICAGO.

To the Editor of The Medical News.

Sir: The fall term of the College of Physicians and Surgeons was opened on the evening of September 23d, at the college building, with music, dancing, and a banquet. The introductory address was delivered by Dr. C. C. P. Silva. The names of 125 students have been enrolled, with promise of several more.

Dr. William M. Tomlinson, of our city health department, in comparing the mortality reports of last year, says that Chicago is the lowest. The figures are as follows: Brooklyn, 23.76; New York, 22.79; Philadelphia, 20.82, and Chicago, 17.44.

An assistant health commissioner will shortly be appointed to succeed Dr. Dixon, but as yet the name of the new appointee has not been made known. The salary is $2500.

The property-owners in the vicinity of Cook County Hospital have sent in a strong protest against the erection of a city morgue in the hospital grounds.

It is said that there are several young physicians in Chicago who have no office, but travel about like doctors in the olden times. They go to drug stores at different hours to meet their patients, who pay very small fees, but by this means avoid the necessity of going to a hospital. It is perhaps a good thing for the sick who cannot afford to have doctors come to the house, and is certainly a new way to build up a practice.

Dr. Joseph Zeisler was elected a member of the German Dermatological Society, while in Berlin attending the International Medical Congress.

It is rumored that preparations will shortly be made to revive the *Chicago Medical Journal and Examiner*, of which Dr. S. J. Jones was formerly editor.

Dr. John A. Benson, Medical Superintendent of the Cook County Insane Asylum, who had charges of mismanagement and the improper employment of patients preferred against him, for contract work at Dunning, was recently exonerated by the commissioners.

Professor H. D. Garrison, in a lecture a short time ago, stated that the crumpled and crushed form of the human ear was originally caused and is now maintained by the habit of lying on the side of the head, and that the habit has resulted principally from the increasing weight of the brain. The question originally seemed to be whether man's ancestors would profit most by large brains or by symmetrical and perfect acoustic apparatus, and nature by selection had promptly decided in favor of a large brain.

The disciples of the new cult, known as "orificial surgery," are all homœopaths. They recently held a

meeting here to effect permanent organization, and hereafter they will convene annually. One of the most prominent of these *oriphysicians* is to deliver a special course of lectures on *orificial surgery* this winter, and all persons interested in this branch may attend for a small fee and receive enlightenment on the formation and removal of pus-pockets.

A clinical society is soon to be formed, known as the Chicago Clinical Society, with Dr. William T. Belfield as its first president.

The opening exercises of the Chicago Medical College and the Rush Medical college took place on September 30th, in their respective amphitheatres. Professor F. C. Schaefer delivered the introductory lecture of the former college, and Professor J. H. Etheridge that of the latter. Professor Roberts, of the Northwestern University, of which the Rush Medical College is a part, spoke briefly, saying that there had been a gratifying increase of attendance in all the departments. He estimated that there are about fifteen hundred young men being educated in the various departments of the university.

Rush Medical College starts out this year with about five hundred students, or nearly one hundred more than were registered at the opening term of last year.

In connection with higher medical education the following extracts from the annual announcement of this college are of interest:

"No student who desires to meet the requirements of the various State Boards, should hereafter enter upon the study of medicine without an ample preliminary education, and the mental discipline its acquirement insures. Such preliminary education should include the study of selected works on English literature, rhetoric, logic, mental science, the fundamental principles of algebra and geometry, and the elements of physics. A knowledge of the rudiments of Latin is essential, since this in a measure removes the difficulty of acquiring the technical language of medical science. After the years 1890–91 no graduate, unless he has studied medicine four years, and taken three courses of lectures of at least five months each, as required in Illinois (and six months each in Iowa), can begin the practice of medicine in these States without passing a rigid examination before the State Board of Health."

The Chicago polyclinic, profiting by the experience of the successful special course given last Spring, has made extensive provision for the accommodation of a large number of practitioners. A spacious amphitheatre, a well-appointed dissecting-room, and laboratories have been erected; and the teaching corps has been strengthened by several valuable additions.

The special course will comprise three distinct series of clinics and demonstrations, as follows:

1. Abdominal and pelvic surgery, with illustrations upon dogs and cadavers, by Professors Senn, Fenger, Parkes, Belfield, and Etheridge.

2. Clinical lectures and demonstrations, in the amphitheatre, in the various branches of medicine and surgery, by Professors Hoadley, Colburn, Hotz, Ingals, Church, and Fütterer.

Professor Moreau R. Brown will perform intubation and demonstrate the technique of the operation; and Professor Charles F. Stillman will give clinical instruction in orthopædic surgery and exhibit recent appliances for the treatment of deformities and diseases of joints, and demonstrate their uses. Professor P. S. Hayes will deliver a course of lectures on electro-therapeutics and the Apostoli method of treating uterine fibroids.

Dr. William G. Eggleston, formerly assistant editor of the *Journal of the American Medical Association*, is, and has been for some time, editorial writer on the *Chicago Herald*.

Cupid cut a large swath at the recent International Medical Congress, said a prominent physician of this city. According to a Berlin paper, one of the results of the Congress was the publication of four hundred engagements of marriage.

One of the ward clubs, of Chicago, has selected for County Commissioner, Dr. J. R. Brandt, who was consulting physician to the Cook County Insane Asylum and Infirmary for three years, and attending physician to the Cook County Hospital for two years. We believe that it will accord with the interests of Cook County if one of the county commissioners is a physician, for the reason that he is well qualified to look after the Insane Asylum, Infirmary, and similar medical institutions.

Professor Walter S. Haines, of Rush Medical College, recently made a chemical analysis of portions of the body of Mrs. Hattie Pettit, for whose alleged poisoning, her husband, the Rev. William F. Pettit, is to be tried at Crawfordsville, Indiana, on October 4th, and has reported to the State's attorney that he discovered strychnine in the parts examined.

American physicians, said a prominent doctor recently, seem to have a mania for prescribing the waters of European medicinal springs, and in consequence many wealthy individuals cross the water, who might, with equal benefit to themselves, patronize American springs. If American physicians would study our medicinal waters and be more patriotic in their recommendations, the health resorts of this country would be more thoroughly appreciated.

The wife of a well-known physician of Chicago recently took charge of her husband's accounts, and when she had gathered a sufficient sum of money she bought eighty acres of land on the South Side of the city, paying $600 per acre. Recently she sold the entire tract for $1,000 per acre, having made exactly $32,000 in three months. Her husband never saw the property nor gave the matter of its purchase or sale any attention.

BALTIMORE.

To the Editor of The Medical News,

Sir: The College of Physicians and Surgeons, rejoicing in a new hospital and new lecture-halls, welcomes its students to more perfect facilities for laboratory studies which are now considered so essential.

The Johns Hopkins Hospital moves steadily onward in its well-chosen path, offering special courses of study which have been eagerly sought even by established practitioners among us. This institution is now beginning to find its true place in our city. It is useless to deny that the relations between it and our medical men were not cordial during the early months of its existence. It was opened with a grand flourish of trumpets, and the daily papers began at once to publish the most extravagant accounts of "wonderful" opera-

tions and cures ascribed to the different professors, and no physician or surgeon in private practice knew at what moment his patients might be spirited away by enthusiastic friends to be treated "better" in the wonderful new hospital wards. Later the professors took offices in our prominent streets, and added private practice and consultation to their hospital duties. The physicians of Baltimore, supposing that these newcomers, of wide reputation and introduced to the public in such an imposing way, would be rivals in both general and consulting practice, naturally could hardly repress certain doubts as to their own future or a feeling that the proceeding was not quite "fair play."

At present, however, there are prospects of harmony. The newspaper notices of extraordinary operations and successes have become infrequent or have ceased to appear, whether in consequence of the earnest remonstrances which have been made with the Johns Hopkins Hospital authorities I am not prepared to say. Personal acquaintance with some of the new professors has shown that they will be a very agreeable addition to our medical circles. The fact that septicæmia and death are not strangers to the new hospital wards has had a somewhat soothing effect on the enthusiasm of the public, and we have learned that while the newcomers must be respected as equals they need not be feared in the fields of either operative work or general medicine.

The dispensary nuisance, which caused an outcry from East Baltimore practitioners, seems to have been somewhat controlled by the care which the Johns Hopkins physicians have shown in the exclusion of well-to-do patients. It is said that such patients are noted at the first visit, and that their pecuniary position is at once investigated by a special agent of the dispensary.

The University of Maryland School of Medicine has endeavored to keep pace with the other schools by extensive repairs of its old buildings and by additions to them. It has also engaged excellent trained nurses for the hospital, and established a training-school in which young women may obtain careful instruction in nursing.

Baltimore has at length begun to follow with earnestness the example of her northern sister-cities in the employment of specially trained nurses in private practice. Many excellent nurses have already been induced to come here from northern training-schools, and others have been obtained from our own hospitals, but the great and increasing demand for educated nurses, without whom the practitioner must always work at a disadvantage, can never be fully met until our own training-schools begin to supply the deficiency.

The Medical and Chirurgical Faculty, which last year took vigorous steps toward the position of the State Medical Society, will soon hold its semi-annual session in one of the towns on the other side of the Chesapeake. It is very earnestly hoped that this society will so unite in itself the divergent interests of the profession that at some early date it may take the lead in securing some remedy for the great and shameful abuses in the department of public medicine. A medical law which shall repress quackery and restrain our colleges from graduating uneducated students is sadly needed. In connection with this it may be stated that the movement toward a lengthened curriculum, to which our colleges appeared to give consent, is likely to end, at least in those institutions where such a change is most needed, in mere talk.

The State Board of Health is making itself useful in resisting the careless pollution of our smaller water-supply at Lake Roland, which lies in a section of the country that is in some respects desirable for summer residence, but which is annually visited by epidemics of dysentery and typhoid fever.

It can hardly be said that our city Health Department is any more efficient under its new Commissioner than it was before he entered with such apparent zeal upon his duties. We have now, it is true, a very imperfect list of cases of contagious disease occurring each week printed neatly upon the back of the health report, but the health-force is still unfitted for its work, and physicians often appeal in vain for the correction of conditions which threaten the health of families and neighborhoods. As was honestly said by one who controlled a sanitary appointment in the city "the offices are for the benefit of the Democratic party," and woe be to the Health Commissioner who attempts to replace an efficient party-worker by an efficient sanitary agent. It is probably true that if physicians stood up persistently against such shameful abuses and showed the public what is done in other cities and what might be done here, they would ultimately win in the contest, but each concerns himself with his own personal advancement, and the politician gets the spoils. It is strange that, where there is such overcrowding of professional ranks, physicians do not claim as a natural right these sanitary posts, which yield a fair income and which are in Great Britain, if I mistake not, filled by medical men or by medical students licensed under the special diploma of "Sanitary Graduate," after a careful education in sanitary matters.

Now that women have so sturdily claimed the medical privileges of the Johns Hopkins it is said that the homœopathic fraternity will try to secure the same privileges. Whether this is true or not, I do not know, but it is not at all improbable. Unfortunately for themselves, that body of practitioners has just experienced a serious schism, and its members differ greatly in regard to the degree of infinitesimality which is necessary for the cure of disease.

The medical societies will shortly begin work for the winter. The Clinical Society met on October 3d. It is the largest medical society in the city and does excellent work. The Medical Association and the Medical and Surgical Society are somewhat smaller; the Academy of Medicine is a feeble but respectable relic of the past; the Obstetrical Society is composed of a very active body of workers; the Society of the Woman's Medical College has but a local interest; and, youngest of all, is the Johns Hopkins Hospital Society, which is composed of the hospital and dispensary staffs, and does work of a high order.

NEWS ITEMS.

The Act to Regulate the Practice of Medicine and Surgery in New Jersey.—The following is an abstract of the Act to Regulate the Practice of Medicine and Surgery in New Jersey, approved May 12, 1890:

1. The Governor shall appoint a State board of medical examiners, consisting of nine members, who

shall be persons of recognized professional ability and honor. The board shall be divided into three classes: the members of the first class holding office for one year, those of the second class for two years, those of the third class for three years. Further, the board shall be composed of five regular physicians, three homœopaths, and one eclectic, and no member shall be in any way connected with a medical college.

2. The board shall hold meetings for examinations at the capital, Trenton, on the second Thursday of January, April, July, and October of each year.

3. All persons commencing the practice of medicine or surgery in New Jersey shall apply to the board for a license; and such applicants shall be divided into three classes—first, those who have been graduated from a legally chartered medical school not less than five years prior to date of application for a license; second, all other graduates; third, medical students taking a regular course of medical instruction. Applicants of the first class shall submit to examination upon materia medica and therapeutics, obstetrics and gynæcology, practice of medicine, surgery, and surgical anatomy; those of the second and third classes, upon anatomy, physiology, chemistry, pathology, materia medica and therapeutics, histology, hygiene, practice of medicine, surgery, obstetrics, and gynæcology, diseases of the eye and ear, medical jurisprudence, and upon such other branches as the board may deem advisable. The questions for the examination of the first and second classes shall be the same in branches common to each class. The board shall not license applicants of the second and third classes after January 1, 1892, until satisfactory proof is furnished that the applicant has studied medicine and surgery for three years, is of good, moral character, and more than twenty-one years of age. Applicants of the third class, after they have studied medicine and surgery for at least two years, may be examined upon anatomy, physiology, chemistry, histology, pathology, materia medica and therapeutics; and if the examination is satisfactory the board may issue a certificate that the applicant has passed a final examination in these branches, and such certificate, if presented when making application for license to practise, shall be accepted in lieu of an examination in such branches.

4. All examinations shall be in writing, and the questions must be, except in materia medica and therapeutics, such as can be answered in common by all schools of practice. If the applicant intends to practise homœopathy or eclecticism, the members of the board of those schools shall examine the applicant in materia medica and therapeutics. The fee for examination shall be fifteen dollars for applicants of the first class and twenty dollars for those of the second and third classes.

5. The board may, by a unanimous vote, refuse to grant, or may revoke, a license for the following causes: persistent inebriety, the practice of criminal abortion, conviction of crime involving moral turpitude, or for publicly advertising special ability to treat or cure diseases which are considered incurable.

6. This act shall not apply to surgeons of the United States army, navy, or marine-hospital service, or to regularly licensed physicians or surgeons called from other States to attend cases in New Jersey, or to any person now entitled to practise in New Jersey.

7. Any person shall be regarded as practising medicine or surgery who shall append the letters M.D. or M.B. to his or her name, or prescribe any drug or other agency for the cure or relief of any injury or disease.

8. Any person commencing the practice of medicine or surgery in New Jersey contrary to the provisions of the act shall be deemed guilty of a misdemeanor, and, upon conviction, shall be punished by a fine of not less than fifty dollars or more than one hundred dollars, or by imprisonment for not less than ten or more than ninety days, or by both fine and imprisonment.

Rules for Conducting Examinations.—1. Each candidate shall present certificates of age, moral character, preliminary education, and time and place of medical studies.

2. All examinations shall be written with ink upon paper furnished by the secretary.

3. The examinations shall continue for two days, the sessions of the first day being from 9 A. M. until 1 P. M., from 2 until 6, and from 8 until 10 P. M.; those of the second day being the same, except that the evening session will be omitted. The final meeting, for the adjudication of the results, shall be held at 8 o'clock P. M. of the second day.

4. A general average of at least seventy-five per cent. shall be necessary in order to secure a license, provided that in no one branch the candidate receives an average of less than thirty-three and one-third per cent. In the latter case, should his total average in all the branches be over seventy-five per cent., the candidate may be immediately granted a second examination in the branch upon which he failed.

5. Each candidate shall sign a pledge that he has neither given nor received any information concerning the examination or used any unfair means. Any candidate found guilty of violating his pledge shall be rejected.

6. No fee will be returned to a candidate after he has commenced his examination. A rejected candidate may be reëxamined within one year without an additional fee.

Corrigendum.

THE PRODUCTION OF IMMUNITY FROM HOG-CHOLERA.

In the article on the production of immunity from hog-cholera (THE MEDICAL NEWS, October 4, 1890), the author would prefer Conclusion 3 to read as follows:

"The sucholotoxins and sucholo-albumins *should be* given in small doses *at intervals*. This, however, is not absolutely necessary, as the experiments show that the proper quantity of substance given at one time will also produce *immunity*, though not so satisfactorily as when the system is gradually accustomed to the poison."

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM SEPTEMBER 30 TO OCTOBER 6, 1890.

CRAMPTON, LOUIS W., *Captain and Assistant Surgeon* (Fort Sheridan, Illinois).—Is granted leave of absence for one month, to take effect about October 1, 1890.—Par. 2, *S. O. 80, Division of the Missouri*, September 30, 1890.

By direction of the Secretary of War, leave of absence granted JOHN L. PHILLIPS, *Captain and Assistant Surgeon*, in Special Orders No. 164, July 16, 1890, from this office, is extended two months.—Par. 3, *S. O. 228, A. G. O., Washington*, September 29, 1890.

PROMOTION.

MORRIS, EDWARD R., *Assistant Surgeon*.—On September 17, 1890, to be Assistant Surgeon with the rank of Captain, in accordance with the Act of June 23, 1874.

ORIGINAL LECTURES.

CHLOROFORM AND THE HYDERABAD COMMISSION.

The President's Address delivered at the Annual Meeting of the Southwestern State Medical Society of Ohio, Cincinnati, October 10, 1890.

BY J. C. REEVE, M.D.,
OF DAYTON, OHIO.

GENTLEMEN: I offer no apologies for occupying your time with some portion of the subject of anæsthetics, even if you are thereby taken again over well-trodden ground. Apologies might easily be found if needed. The differences of opinion and practice which prevail as to the two great anæsthetics are far greater than ever, and also exist among practical men as to remedies whose action is fully and clearly understood. Whenever this subject is opened, questions of immense practical importance present themselves—questions which, in the present state of our knowledge, are impossible to answer. The limited portion of the subject chosen for to-night not only needs no apology, but it demands attention. The experiments of the Hyderabad Chloroform Commission and the conclusions drawn from them constitute the latest phase in the history of anæsthetics. They demand examination not so much as a contribution to knowledge we already had, but because the results obtained by experiment differ so widely from those of other observers; because the changes of doctrine introduced are wide and sweeping; because the conclusions formulated are stated with a positiveness which challenges scrutiny. When I add that the teachings of this Commission, if accepted, increase the responsibility and add to the anxieties of everyone who administers an anæsthetic; that further, if any reliance is to be placed on clinical experience the teachings are fraught with danger to patients, I know that you will agree with me that they should be submitted to a close and searching examination.

The Hyderabad Chloroform Commissions owed their existence to the liberality of the Nizam of Hyderabad and the enthusiasm of Surgeon-Major Lawrie, a disciple of Syme and a warm supporter of the Edinburgh school. The investigations were made in a country where there are no restrictions upon experiments with animals, and the commissions had, therefore, command of ample material. By the first commission, held in 1888, 141 dogs were killed by chloroform inhalation, the symptoms, and especially the sequence of symptoms, being carefully noted. The chief conclusion reached was that "it is impossible for chloroform vapor to kill dogs by acting primarily on the heart, and this holds good no matter in what doses or in what manner the poisoning is induced."[1] This experience is so diametrically opposite to that of others, it may be said to that of all experimental physiologists the world over, that it called forth strong comments, especially from the *Lancet*. The criticism led to the formation of a second Commission, and by the liberality of the Nizam, who gave £1000 for the purpose, Dr. Lauder Brunton was added to the Commission, and went to India and took part in the investigation. By this second commission about 600 animals, mostly dogs, were sacrificed. The mode of death was studied, but attention was principally given to the effect of chloroform inhalation upon the two great functions of respiration and circulation, and especially to determine which ceased first. The result is stated to have been invariable—in every instance the respiration stopped before the heart. This is the briefest possible statement of the work of the Commission, and it is the "practical conclusions" drawn from this work that I now propose to examine. In view of some of the names attached to these reports my effort may be deemed presumptuous. I can only say that the day is past when a name will cause acceptance of a doctrine which is not in accord with facts. We no longer live in the age when men were content to be wrong with Nature that they might be right with Galen.

You will see that of the two modes of study open to us as to the action of medicines—experiment upon animals and clinical observation—the Commission has pursued one and only one. My study of the subject has been, and must be to-night, solely in the other. I am not an experimental physiologist. I am not, therefore, about to occupy your time with details of "tracings" and of "blood-pressure." And inasmuch as the results obtained by the Commission fail to agree with those of other observers, their work must be submitted to other experimenters for reëxamination. This has already been done, and I refer you with pleasure to the excellent paper by Drs. Wood and Hare for a criticism upon this side of the subject.[2] My object is to compare the results obtained by the Commission with observations made at the bedside, and the conclusions arrived at by them with clinical experience. When experiment upon animals and observation upon man agree in results we are sure —very sure—of our position. When these two modes of study do not agree, however, there can be no hesitation as to which we are to follow. The bedside is the last court of appeal for the physician and surgeon.

Permit a few general observations upon the second Commission before proceeding to particulars.

1. The Commission was organized *for a purpose*, which purpose was plainly stated. The object was "to show

[1] Lancet, February 22, 1890.

[2] THE MEDICAL NEWS, February 22, 1890. See also: "Remarks on the Second Report of the Hyderabad Commission, by the Glasgow Committee of the British Medical Association." British Medical Journal, June 14, 1890.

by experiments upon dogs that in death from chloroform the respiration always stops before the heart."[1] Without commenting at length upon this, I suggest that delicate instruments of observation, kymographs or what not, will yield no reliable results if that more delicate instrument which directs and observes them, the human brain, be clogged in its action by preconceived opinions. The scientific method is to make the experiments first and the doctrines afterward.

II. The report throughout shows no recognition of the possibility of more than one kind of death under chloroform inhalation. The effort was to discover whether danger to life arises "from failure of the heart *or* failure of the respiration."[2] From one end to the other the tone of the report is that death by the respiratory function necessarily excludes death by the heart. They seem to be looked upon as mutually antagonistic, and there is no recognition of the possibility that death may occur by either channel, or that both functions may cease simultaneously. Nearly twenty-five years ago I made and published a careful study of all the then recorded cases of death under chloroform.[3] That study was made largely in regard to etiology, and when I still held the belief that death was almost always the result of faulty administration. I learned then that the symptoms in the fatal cases varied widely, and that there was more than one path to the lethal end. That death may occur from long continuance of the inhalation—an over-administration of chloroform—is certainly possible, but it could only be brought about in this way by gross carelessness or inattention, and it is doubtful if the record of any clearly-marked cases of this kind can be found. The following forms of death are, however, to be plainly distinguished in looking over the reports of fatal cases:

1. Sudden death during the stage of struggling or excitement, in which it is difficult to say just where the process commences. There is great excitement of the nervous system, tetanic contraction of the muscles of the chest, with suspended respiration followed by very deep inspirations, and sometimes general convulsions. The frequency with which death has occurred at this part of the inhalation marks it as the most dangerous stage of the process.

2. Death by paralysis of the respiratory centre, the heart having been observed to continue beating after respiration had ceased. Ten deaths occurred in this way out of forty carefully observed cases.

3. Death by paralysis of the cardiac centres. The pulse fails, the divided vessels suddenly stop bleeding, the heart ceases to act, while respiration has been observed to continue for a time.

4. Death by simultaneous cessation of respiration and heart-action.

Of the modes of death, that in which the symptoms on the part of the circulation preceded or predominated was so frequently observed that the doctrine became current that death under chloroform was always cardiac death.

III. The exceedingly small number of observations upon which the very positive doctrines and important conclusions of the Commission are based. Not many more than one thousand experiments were made, and because a certain event did not happen in that number of experiments it is claimed that it never happens. The weakness of this point is recognized and acknowledged by Dr. Brunton himself.[1] Had the experiments been ten thousand instead of one, the argument would still be weak. There were 28,000 administrations of chloroform in one corps of the Confederate army without a death. The distinguished surgeon, Hunter McGuire, had 15,000 administrations, and then a death. *Per contra*, an English hospital had one death in 200 administrations. But here, as everywhere, the tendency is to draw conclusions solely from personal experience. Whenever the subject of anæsthetics comes up in a medical society someone is sure to arise with the oft-repeated formula: "This is my plan; I never had an accident; follow this plan, which is safe beyond a doubt." The "plan" is, usually, a glass of whiskey before the administration. There can be easily adduced from clinical records more than a dozen cases in which sudden death took place when an alcoholic stimulant had preceded the administration. There are several cases of death under ether when the same had been given. The personal experience of Surgeon Lawrie is certainly marvellous, and he may well argue from it. He tells us that for fifteen years he has administered chloroform from five to ten times daily.[2] Taking the mean, this would give over 40,000 administrations, a number which surpasses that of many army statistics and is more than half the number of inhalations during our war. That his good fortune in having this number of cases without a death was due alone to one point, as he claims, "watching the respiration," we cannot accept. There was no such single method followed as a safeguard in the Confederate army.[3] Still, Surgeon Lawrie's experience was with human beings.

IV. The rigid application by the Commission, of occurrences observed in animals to the human subject. This is the weakest point of all, and immediately called forth a host of protests. Because in dogs death under chloroform always takes place by the respiration it therefore must always do so in man, is weak reasoning. Yet there has been such reasoning all through the history of anæsthetics. Because, in the majority of cases, death occurred thus in animals was formulated the doctrine, which stood for a long time unquestioned, that in man ether-death is always by the respiration and chloroform-death is always cardiac. Sure of my ground clinically, and fortified by the high authority of Kappeler that "ether-death does not differ materially from chloroform-death," I stated in 1882 that "ether, in the human subject, may cause death as suddenly, as unexpectedly, and in the identical manner that chloroform does."[4] An

[3] In 1882 (Holmes's Surgery, American edition) I suggested that *climate* might explain the differences of experience with anæsthetics. This explanation might apply between the north-eastern and southern parts of our own country, and between England and India. But it entirely fails to apply between Great Britain and continental Europe, *provided*, that we know all the deaths that have occurred under chlorofom in France and Germany.

[4] Holmes's Surgery, American edition, vol. iii.

eminent surgeon of Philadelphia questioned the truth of the statement, and in reply I published the clinical proof.[1] As this work was mentioned at the late International Congress and the proof accepted by Professor H. C. Wood in his address, it is to be presumed that the fact will be hereafter generally accepted. The truth is evident that the results obtained by experiment on animals cannot be absolutely and universally applied to man, and it is astonishing that men claiming to be scientists should presume to make such application. It utterly breaks down before such potent facts as that dogs may be killed by elaterium without being purged; that pigeons bear enormous doses of morphine; and that goats and rabbits eat belladonna with impunity.

I select now some particular doctrines from the "Practical Conclusions" of the Commission, which they present in the most positive manner for the guidance of the profession. Carefully reading over the fifteen paragraphs in which these conclusions are given, it is surprising how many of the conclusions were well known to the profession long before, and which are therefore neither new nor necessary. It did not need a commission to tell us that the recumbent position is necessary for safety—the danger of any other has long been recognized. It certainly was unnecessary to tell us that the respiration should be free and unembarrassed. A tyro in physiology would recognize that in a patient to whom respiration and circulation alone remained of life, any interference with breathing, as by resting on the chest to restrain struggling, or by shutting out the air with an impervious towel, would be highly dangerous. This danger has been recognized and warning was given far back and all along in the history of anæsthetics.

The especial doctrines taught by the Commission, repeated and emphasized, are that in the administration of chloroform the respiration is the only thing to attend to, death always taking place by that channel; that disturbance of this function always and first indicates danger;[2] that by watching the respiration danger can be foreseen and averted; that "the utmost attention to the respiration is necessary to prevent asphyxia or an overdose." (See II.) The ninth section reads: "The administrator should be guided as to the effect entirely by the respiration. His only object while producing anæsthesia is to see that the respiration is not interfered with."[3] This doctrine carries with it another: that it is *not* necessary to watch the pulse. This is boldly stated by Surgeon Lawrie: "The pulse is of no value as a sign of approaching danger."[4] This is the doctrine of Syme, of Lister, and of the Edinburgh school. In connection with this we are asked to believe two things, if we can: "Pallor and loss of pulse do not indicate that chloroform has any direct effect upon the heart, but that it has been given in such a way as to interfere with the breathing;" and, "If part of the chloroformist's attention is to be directed to the pulse an important element of danger comes into the administration."[1] Lauder Brunton reiterates the statement.[2]

The number of competent observers who have testified to the falsity of these doctrines would be enough to settle the question. At the debate in the Medical Society of London which followed Dr. Brunton's address, several bore witness to the frequency of failure of the pulse and heart-action before respiration was affected. Three experienced chloroformists of London hospitals gave in print testimony to the same effect.[3] Two cases were detailed in which there was positive observation that respiration went on after the heart's action had ceased.[4]

But I will adduce some testimony given to the profession many years ago, and give some clinical facts. The first three cases of death under chloroform all showed signs of sudden cessation of the circulation Of the 50 fatal cases given by Snow, 18 took place by cardiac paralysis and in 12 it is distinctly stated by the observers that respiration still continued after the heart had ceased to beat, or after decided failure of the pulse had awakened alarm.[5] Of 21 cases of dangerous symptoms observed by Anstie, in 16 a change of pulse, with sudden pallor, was most prominently noted, and was the first symptom.[6] You have had two well-marked cases of this kind here in Cincinnati under the observation of my friend, Professor Dawson: a sudden cessation of bleeding at the wound first called the operator's attention to the state of the patient.[7]

Permit me to detail, with the utmost possible brevity, three cases from an observer whose competence, accuracy, and honesty cannot be called in question:

Case I.—Patient was a woman, aged twenty-five years; under no apprehension or fear. The administration was for flexion of a contracted extremity. Pulse was 96, respiration 24. After inhaling chloroform for five minutes, there were muscular contractions, and the pulse rose to 102. In seven minutes there was muscular relaxation; reflex action upon touching the cornea was almost abolished; pulse regular, 96. Administration continued, and at end of fifteen minutes the radial pulse became suddenly intermittent, and, at the same time, the face became pale. The patient respired at this time peacefully and regularly. The administration was immediately discontinued and the patient recovered.

Case II.—A woman, aged forty years. Chloroform was given for the removal of a tumor from the axilla and she feared the anæsthetic very much. A physician experienced in administration watched the pulse and respiration. Soon after beginning the operation, and without any hæmorrhage, the three medical men present observed that the patient's countenance became deathly pale; the one watching the pulse announced its disappearance, and soon afterward respiratory move-

[7] Transactions of the American Surgical Association, vol. II., 1884.

ments were no longer visible. Bleeding from the wound had entirely ceased. The mouth was easily opened; there was no falling back of the tongue. This patient was rescued with great difficulty.

Case III.—A woman, aged thirty-four years, with lupus of the face and arm of many years' standing. For this she had undergone seven curettings, each time under the influence of chloroform, and without any unusual symptoms from the anæsthetic. Chloroform was given for still another operation, by means of the Esmarch wire-mask. It is expressly stated that great care was taken not to interfere with the respiration, which, indeed, is quite impossible with this apparatus. Pulse and respiration were watched, and both remained regular and good up to the close of the operation. After the operation, and about two minutes after removing the chloroform, the patient suddenly began to draw the head slowly to the right, the face became corpse-like, the eyes opened widely so that the fully dilated pupils could be seen; almost at the same time the pulse ceased, the respiratory movements became slow and superficial, and, after some seconds, entirely ceased. She was dead.

These observations are by Kappeler.[1] In the last case it is probable that the pulse and respiration ceased together, but the testimony is no less clear that the respiration does not always give warning of danger. The fact is, that, in the human subject, death by cardiac paralysis has occurred so much more frequently than that by respiratory paralysis that the doctrine became current that chloroform-death is always cardiac-death. The doctrine is false. Chloroform sometimes paralyzes respiration first, as ether sometimes first affects the heart.

You will have noted the sudden change of countenance observed in these cases; it is, of course, a symptom which cannot be seen in animals. In man it has so often been the first symptom to attract attention that it presents the strongest clinical claims to consideration. In the three cases of danger which it has been my lot to witness, this symptom was present, and first awakened alarm. Thus does a master-hand draw the picture: "Without warning, generally, also, without disturbance of the respiration, the countenance takes on a waxen hue, as if under the stroke of a magic wand; the lineaments are decomposed, the cornea loses its lustre, and the fully dilated pupils become motionless; the jaw falls. At the same time the radial pulse ceases, and the heart-sounds are imperceptible, or extraordinarily weak; the opened arteries cease bleeding. With cessation of the heart's action, the respiratory movements terminate without cyanosis or dyspnœa, or a few sighing and spasmodic inspirations continue after the heart has ceased to beat."[2]

Looking at the clinical side of the subject, there is a striking concurrence of testimony as to the suddenness with which danger appears under chloroform, and as to symptoms on the part of the circulation, preceding all others. In view of its amount and character, it is incomprehensible that the doctrine could ever be held that the respiration always gives warning of danger, and that death comes always by that function. The cases giving evidence upon these points are so numerous that there would not be time to detail them to-night. But, in view of the evidence adduced, and of a few well-marked cases detailed, how does the statement of the Commission appear, that "the fear of chloroform paralyzing the heart is based on the results of laboratory experiments rather than on clinical experience?"[1]

The second doctrine of the Commission which demands consideration is that death under chloroform is always from an over-dose. The official report warns against danger from an "over-dose." Surgeon Lawrie says that the experiments have *proved* that "death from chloroform is always due to an over-dose."[2] What is an over-dose of chloroform? Evidently, when the patient inspires air carrying more than a certain small amount of chloroform vapor. Sudden death frequently occurs in animals breathing a supercharged atmosphere, and in man it has often followed a single deep inspiration. The necessity of care to avoid this danger is plainly stated by the Commission.[3] But this is not new. The danger of charging air with more than a small percentage of chloroform has long been recognized. It was taught by Snow, who believed that safety would be assured if the amount of vapor was kept down to four or five per cent. This doctrine underlies and sustains the use of all inhalers—instruments which mechanically prevent the presence of more than a certain amount of vapor. But it has not stood the test of clinical experience; death has occurred with all sorts of inhalers, even in the hands of the inventors who had vaunted their efficiency.

There is another way in which a patient may get an over-dose of chloroform, namely, when the administration is continued beyond the limits necessary for the surgeon's action and until respiration and cardiac action cease. It is a form of death difficult, if not impossible, to find in clinical records. And surely it is not necessary to warn against a danger so evident as this, which could only be caused by gross maladministration. Yet, this the Commission does. "The anæsthetic should never, under any circumstances, be pushed till the respiration stops."[4] Surgeon Lawrie says that there is not the least danger if the inhalation "is stopped directly the state of the cornea shows that the patient is 'under.'" This he repeats in italics; and again italicizes from Syme, as an infallible rule for the safe administration of chloroform, that "*we never continue beyond the point when the patient is fully under the influence of the anæsthetic.*"[5] Now, let us throw upon this doctrine the electric light of clinical experience. About fifty per cent. of the deaths under chloroform have taken place before the stage of complete anæsthesia has been reached![6] Some of them have occurred at the very beginning of the administration, after an inhalation of only a few seconds. Within so short a space of time as that, death occurred in four of Snow's fifty cases, and in five more it took place within a minute. Need I adduce any more evidence that cessation of administration when

the cornea is rendered insensible will not obviate danger? And how do these early and sudden deaths bear upon the preceding doctrine that death is always by the respiration? Can death within a minute be caused in the human subject by any interference with respiration?

The last and most important doctrine of the Commission is that there is "no doubt whatever that, if the above rules be followed, chloroform may be given in any case requiring an operation with perfect ease and absolute safety." The only new rules laid down, it will have been observed, are the one positive, that the respiration alone should be watched, and the one negative, that the pulse should not be watched. The inference from this position of the Commission is that all deaths have been the result of bad administration. Surgeon Lawrie does not avoid the issue. There is never the least danger, he says, "when the chloroform is properly administered;"[1] and he describes a death as caused by the administrator, which bears no likeness whatever to what is seen in life, and is in strong contrast to the graphic picture drawn by Kappeler. It is against this doctrine and its corollary, so untenable in the light of clinical experience, so dangerous to patients, so momentous in their bearing upon the conscience and the material interests of the profession, that I most solemnly and earnestly protest. It is but just that when a man loses a patient under an anæsthetic, he should be required to show that due care was observed and all precautions taken: but to hold that the death is *prima facie* evidence of want of skill or carelessness is a monstrous doctrine. See where it carries us—to the unavoidable conclusion that many of the best surgeons of the world have caused deaths which might have been avoided; and that men who led in the study of this subject, who have devoted their lives to it, did not know how to administer the remedy properly. Simpson, and Snow, and Clover, and Kappeler, all had deaths—therefore, they violated the rules of safe administration.

I protest, in the interest of patients, against the doctrine that chloroform can be administered with absolute safety. If this procedure is to be looked upon as no more dangerous than giving a drink of whiskey and water, as has already been claimed, there will be a more frequent recourse to it, and lives will be sacrificed in consequence. The doctrine cannot be accepted without ignoring a vast amount of evidence, both experimental and clinical—evidence which outweighs all theories and all doctrines, no matter whose names may be appended to them. And, beside the few cases detailed to you to-night, even if there were no more, how does the statement appear, that "the fear of chloroform has arisen not from clinical observation, but from the results of experiments upon animals having been wrongly interpreted."[2]

No theory in science deserves a moment's consideration which does not cover all the facts. Now, the Hyderabad Commission has formulated in the most positive terms a theory of death under chloroform without any consideration of a most important class of cases—cases which, with our present knowledge, defy explanation, yet without a consideration of them no study of death under anæsthetics can be complete. I allude to those in which the dangerous symptoms came on some time after the inhalation had ceased. Every administrator of chloroform should bear in mind the "residual air" of the lungs, which is to the tidal air as more than five to one. Of course, this residual air being charged with chloroform, the effects of the anæsthetic will deepen after the tidal air has ceased to carry more vapor into the lungs. But in the cases referred to, danger set in at a period too remote to be accounted for in this way—several minutes after the administration had ceased, breathing having continued long enough to change the air in the lungs several times. In Kappeler's case, given above, two minutes had elapsed. In case 50 of Snow's collection, the surgeons washed their hands, returned to the bed, and, seeing that the patient was all right, left the ward, to which they were hastily recalled to see the patient die. So important is the bearing of these cases upon the doctrines considered to-night that I will give a brief report of three of them.

Case I.—Adult male. Operation under chloroform for fistula in ano, Cincinnati Commercial Hospital, Dr. Thomas Wood, operator. After the operation the patient *aroused sufficiently to answer one or two interrogations.* The order had been given to remove him from the amphitheatre when he was seen to gasp, and death rapidly followed in spite of artificial respiration. *At least three minutes* elapsed from the time the administration ceased until dangerous symptoms set in.[1]

Case II.—Another Cincinnati case, on the testimony of a medical man present at the operation. Young adult male. Operation under ether for extirpation of eyeball. The operation was completed and the patient in good condition. The surgeons were engaged in examining the specimen when suddenly their attention was attracted to the man and he was found to be in a most dangerous condition, and was rescued only by vigorous measures.

Case III.—I administered the A. C. E. mixture to a middle-aged man, upon whom my colleagues of St. Elizabeth's Hospital performed an operation on the bones of the leg. The operation had continued some time; all was going on well with the patient. I closely observed the pulse and respiration. So long a time had elapsed since I had held the sponge over the mouth and nose that it needed replenishing. The "sister," who held the bottle for me had gone away and placed it on the dresser several paces away. I walked to it deliberately, added the anæsthetic to the sponge, and returned, but was horrified to see the aspect of death on the man's face. No respiration was visible; no pulse to be felt. Quicker than can be told, his head was lowered, the tongue pulled out, and the best attempts possible were made at artificial respiration. After a time, which seemed an age, and when there seemed no more ground for hope, he drew a breath, and then slowly recovered.[2]

I have selected these cases, from among others of the same kind, because they occurred here close to you; because they concern three different anæsthetics, and because of their great importance. The Commission

[2] Official Report, Lancet, January 18, 1890; and Lauder Brunton, International Congress, Lancet, August 16, 1890.

[1] Cincinnati Lancet and Observer, 1871.

[2] It may be of interest to state that a few weeks afterward I again administered the A. C. E. mixture to this patient. I had no hesitation in doing so after a hypodermic injection of morphine and atropine, and there was no trouble.

would doubtless say, in regard to my case, that my attention was withdrawn; that had I been "watching the respiration" the dangerous symptoms would not have occurred. But, before leaving the side of the table, I had ceased administering the anæsthetic for more than two minutes. And this important class of cases receives no consideration from the Commission. They merely allude to them as those "in which dangerous failure of the heart *is said to have occurred* some minutes after the administration of chloroform had ceased."[1] This is thrusting facts aside without examining them. What bearing do these cases have upon the doctrine of the Commission that there is no danger in the administration of chloroform if only the respiration be kept free and unobstructed? Can such a doctrine exist in view of these cases?

There is a doctrine, however, with which these cases harmonize. It is one that I presented several years ago, which further study has not caused me to abandon.[2] That doctrine is, that all anæsthetics are uncertain and irregular in the manifestation of their effects, and chloroform more so than any other.

A careful study of the whole subject shows that death cannot always be foreseen or averted. It has taken place in the hands of the most experienced administrators, in institutions where every precaution was taken and every means of rescue at hand. It has occurred with inhalers and without, to patients of all ages and when in the best possible health. Disaster has come when the anæsthetic was given for the most trivial operations, before surgical proceedings have commenced, during their progress, after their completion, and after the inhalation had ceased. A like sudden and unexpected death has been of frequent occurrence in animals, according to all experimenters, except the Hyderabad Commission.

In view of all this clinical and experimental evidence, and of the concurrent testimony of the best authorities of the world,[3] can we accept the doctrine that chloroform is a safe remedy? I disclaim any partisan feeling in the matter. If any man, after making a careful study of the clinical evidence, and in view of the disadvantages of ether, and of the fact that it, too, has its death-roll, shall elect chloroform as an anæsthetic, I have no denunciations for him. But for myself, such a study convinced me that it is uncertain in its action and more dangerous than other agents at command. Nothing in professional life ever caused me so much pain as the forced abandonment of this anæsthetic. And now I believe that if the doctrine of the Commission prevails, and if there be in consequence a more general resort to chloroform there will be disaster as the consequence.

I would devote some attention to the logic of the Commission's report, but lack of time will not permit. For the same reason I cannot enter upon some points of great practical interest. I should especially like to compare the results of the Commission with those obtained by Professor H. C. Wood, and with recorded clinical observations, and to show that in regard to shock under chloroform, experiment upon animals and bedside experience do not agree.

[1] Official report, Lancet, January 18, 1890.

[2] Holmes's Surgery, American edition, 1882, vol. iii. p. 542.

[3] Ibid.

I ought, perhaps, to dwell upon the assumption of the Commission that watching the respiration and resorting to means for its continuance, will always carry the patient safely over the danger.[1] I am saved the trouble by adducing a single case, published in the same number of the same journal with one of the reports of the Commission. The patient, a woman aged twenty-four years, had taken chloroform several times; was in good health; and had no fear of the operation or the anæsthetic. The administrator had given chloroform about 700 times; Skinner's inhaler was used with twenty drops of the anæsthetic. Immediately upon adding a fresh supply of chloroform the patient suddenly stopped breathing. The tongue was drawn out and artificial respiration by Sylvester's method instituted and continued for half an hour. It was in vain; she was dead. An autopsy showed that all the organs were healthy, and gave evidence that the heart continued to act after breathing ceased.[2] Here, then, side by side with the report of the Commission, is a case of death by the respiratory function, in which measures of rescue were immediately resorted to by experienced men in a hospital, without result. There is sometimes a grim irony in facts.

I will conclude by giving a series of "practical conclusions," derived from studies of the subject by experiment upon animals, which do agree with observations upon the human subject. And I consider it a matter of no slight congratulation that they were presented at the late International Congress by one of our countrymen, Professor H. C. Wood, in his address on Anæsthesia.[3] They have been lately published in nearly all the journals, but they will bear repeating. The closest examination fails to detect any flaw in them, or to find any point which is not supported and which cannot be substantiated by clinical records:

1. The use of any anæsthetic is attended with an appreciable risk, and no care will prevent an occasional loss of life.

2. Chloroform acts much more promptly and much more powerfully than ether, both upon the respiratory centres and upon the heart.

3. The action of chloroform is much more persistent and permanent than that of ether.

4. Chloroform is capable of causing death either by primarily arresting the respiration, or by primarily stopping the heart, but commonly [sometimes] both respiratory and cardiac functions are abolished at or about the same time.

5. Ether usually acts very much more powerfully upon the respiration than upon the circulation, but occasionally, and especially when the heart is feeble, ether is capable of acting as a cardiac paralyzant, and may produce death at a time when the respirations are fully maintained.

6. Chloroform kills, as near as can be made out, proportionately four or five times as frequently as does ether.

ORIGINAL ARTICLES.

PROPHYLAXIS OF TUBERCULOSIS.[1]

By C. W. STROBELL, M.D.,
of Middletown Springs, Vermont.

Tuberculosis, according to reliable statistics, is responsible for one-seventh of all deaths that annually occur in this country. It is a disease before which we, as physicians, have thus far stood well-nigh powerless, the subject's doom being sealed in our minds simultaneously with the confirmation of the diagnosis. It is in vain that alleged specifics and much-vaunted discoveries are tried. In vain have gaseous enemata, oxygen inhalations, superheated air, and nauseous fish-oil flashed spasmodically upon our therapeutic horizon, momentarily lighting up the gloom with a fitful glare, only to plunge us into deeper therapeutic darkness.

In order that we may be thoroughly in sympathy with our subject, and fully appreciate the rapid and salutary changes which the theories concerning the pathology of tuberculosis have undergone, let us briefly review its literature since 1865, previously to which investigators were groping in a dense theoretical fog. Villemin, in 1865, startled the medical world by the artificial production of tuberculosis, exciting renewed and intense interest in the pathology of the disease. He inoculated animals by inserting tuberculous matter beneath the skin through a small incision. One month later it was found that, with few exceptions, general tuberculosis had set in. Artificial tuberculosis, it was ascertained, could be easily generated in rabbits, guinea-pigs, oxen, sheep, goats, and monkeys. Cats and dogs proved not very susceptible, and in the case of a cock and a dove the experiments entirely failed. Villemin also produced tuberculous infection by injecting a watery suspension of tubercle into the bronchi. These researches constitute the first link of the chain of brilliant experiments that are rapidly guiding us to a solution of this problem in pathology.

With regard to the material inoculated in the later experiments Gee[2] says:

"Villemin used fresh tubercle, but soon afterward Andrew Clark and Waldenburg succeeded in rendering rabbits tubercular by inoculating them with materials other than tubercle. It was next found that not only animal tissue, but even the vegetable, such as a cotton seton, or a piece of cork, would set up tuberculosis. And lastly, the fact was discovered that a simple wound into which nothing was inserted would suffice to generate tubercle in rabbits, guinea-pigs, and certain other animals. However, Sanderson, in 1868, showed that of all the means of producing artificial tubercle by inoculation, none is more certain or more active than the material taken from the diseased glands of a living animal already infected. The dose required is almost infinitesimal. If a diseased gland is squeezed into a little distilled water in a capsule, and the slightly turbid liquid injected, results are certain. Both Sanderson and Wilson Fox, in 1868, discovered that when non-tubercular matters are inoculated they become encapsuled by cheesy matter formed beneath the skin, so that the difficulty of explaining the subsequent tuberculosis is not so great as it seems at first. The tubercles follow, not the material inoculated, but the inflammatory products which surround it. Cohnheim inferred that the infectious matter was always caseous pus. But the inflammatory products around the wound of inoculation are not always cheesy, although they are usually so.

"Therefore the infectious virus which excites the general tuberculosis is not introduced from without, but is generated by the animal itself. The animal must possess a tubercular diathesis, and if this is present any kind of inflammation, set up in any way, may call forth tuberculosis."

This summing up of the status of the case in 1884 is interesting when viewed in the light of recent developments, for close upon the heels of these investigators came Klebs, Aufrecht, and Baumgarten, with the theory of the bacillary form of the virus. Schüller and Toussaint described it as a micrococcus.

The announcement of the discovery of the specific bacillus of tuberculosis by Koch was at first received with incredulity, and in some quarters with prejudice, which, however, disappeared as the confirmatory evidences multiplied, until to-day there seems to be no reason to doubt the specificity of Koch's bacillus, although as yet the precise action or manner of infection does not seem clear, *i. e.*, does the bacillus mechanically infect by its presence, as in the case of a cotton seton and various organic and inorganic materials, or by its secretions? This question is of vast importance regarding the therapeutics of the disease, for, could the view be proven (and in my opinion it is the true solution) that the secretion of the bacillus is the virus, then there opens before us a glorious prospect of being able to cure tuberculosis by neutralizing the virus. Already has Koch's discovery borne practical fruit in the prophylactic measures we are enabled to apply intelligently.

The pleura, peritoneum, arachnoid, and even the pericardium may be the seat of miliary tuberculosis; but it is generally noted that the lungs are the organs first attacked, and that it is extremely rare for tubercle to exist in any organ without being also present in the lungs.

The *Medical World*, June, 1890, states that:

"Tubercle bacilli are found in phthisis tuberculosis, scrofula, lupus, and pearl disease. In enteric disease they can be detected in the dejecta; in tubercular disease of the urinary apparatus, in the urine; in tubercular meningitis, in the nasal secretion; in phthisis they infest the expired air, the sputa, the secretions of laryngeal and pharyngeal ulcers, and the pus of anal fistulæ. In

[1] Read at the semi-annual meeting of the Vermont State Medical Society, June, 1890.

[2] Quain's Dictionary of Medicine, 1884.

scrofula they swarm in the pus of diseased joints, and in the discharges from scrofulous ears. They have also been frequently discovered in lupus vulgaris, which is now considered by many pathologists to be a tuberculosis of the skin. In all these instances they are capable of cultivation; and many of the lower animals can be inoculated, which tends to prove that the inception of tuberculosis depends upon the passage of the living bacillus from one organism to another, the peculiar pathognomonic changes being consequent upon either its mechanical presence or the virulent character of its secretions."

The next question that concerns us is, What is the primal source of the bacillus of tuberculosis? Investigations thus far point very strongly to the bovine species as responsible for the disease in the human family. As evidence of this origin we will cite the case of one of our foundling homes, where an endemic of acute miliary tuberculosis broke out with great fatality. It was at length suspected that the dairy attached to the institution was the source of contagion. Investigation revealed that three-fourths of the cows were infected with tuberculosis. The milk was condemned as unfit for the use of the infants, and given to the swine, of which there were twenty-five or thirty. It was observed that with the withdrawal of this milk a marked improvement began in the health of the infants, which continued so far as tuberculosis was concerned. But there is a sequel to this, namely, that the swine that were given the rejected milk sickened, emaciated, and finally died. The order was given to kill all the cattle and swine upon the premises, which was followed by thorough disinfection and a complete restocking.

Although innumerable cases may be cited of the infection of certain of the lower animals by man through the ingestion of his excretions in various forms, there is not one instance, so far as I know, of such infection of an animal of the bovine species, which is probably due to the purity of their food. So that in the latter animals the bacillus seems to arise spontaneously.

Admitting, then, the bovine theory of the origin of tuberculosis, let us briefly enumerate the methods of infection beginning with the originators. Infection from the cow may be from either the meat, the milk, or the sputa. By the ingestion of tuberculous meat and milk man is infected, provided that a proper soil exists. By hereditary predisposition, and the ingestion of tuberculous milk and sputa, calves are infected, and propagate the disease in the herd.

Infection from man to man ranks next in importance, and this is either directly by the ingestion of sputa; or indirectly by the use of tuberculous pork and poultry. To the omnivorous habits of our barnyard fowls and of swine, is due the fact that they are very susceptible to this disease.

The house-fly, too, is by no means innocent, as shown by the experiments of Drs. Spillman and Houshalter.[1] Flies that had been seen to enter spittoons containing the sputa of phthisical patients were caught and placed in a bell-jar. On the following day several of them were dead. An examination of the abdominal contents and the excrement of these flies showed the presence of many tubercle bacilli. The authors point out the wide dissemination of the disease which may take place in this manner. It was clearly shown by Professor Dixon, of the University of Pennsylvania, that calves and pigs fed upon milk infected with tubercle bacilli, became tuberculous. The gastric secretions of the dog are said to be a greater defence against the successful invasion of the bacilli than are the similar secretions of man, but a healthy dog which Professor Dixon fed for several days on the meat of a tuberculous cow soon began to lose flesh, and died a few weeks later of tuberculosis.

Dr. Henry Behrends, a noted Hebrew physician and scientist of London, regards the freedom of the Jewish people from phthisis as due to the religious rules concerning the choice and killing of cattle, and the sale of meat. Dr. Behrends[2] writes that of 13,116 beeves slaughtered for the Hebrew trade in London in six months, only 6,973 came up to the peculiar Jewish requirements, and that the average rejections for five years had been 40 per cent. But the rejected beeves are often used by the Christian butchers. He also makes the astounding statements that in a large practice of over thirty years he has never met with a case of consumption among the members of the Jewish faith, and that other Hebrew physicians have had a similar experience.

The prevention of the disease seems possible by two simple measures. First, the devitalization of the sputum of consumptives, for the desiccated tubercle bacillus retains its vitality. Second, the legal inspection of all dairies at regularly stated periods, and the slaughtering of cattle for food purposes under the supervision of a regularly qualified and legally appointed veterinarian, who shall issue a certificate upon "proof-meat," and be held responsible for the wholesomeness of such meat.

As regards the sputum, devitalization should be secured almost immediately after being expectorated. Destruction by fire is the most convenient, safe, and certain method of devitalization. The patient should expectorate upon pieces of newspaper, which, upon receiving the sputum, are twisted and dropped into a receiver, which should be emptied into the fire as often as every three hours; or the papers may be immediately dropped

[1] New York Medical Record, November 12, 1887.
[2] Medical World, February, 1890.

into the fire. In view of the results of the experiments with the house-fly referred to above, it is unsafe to employ a sputum-cup during summer, or at any time in fact, as its contents are not, as a rule, thrown into the fire, which is the devitalizer *par excellence*. The sputum-cup is usually emptied into the slop-jar or out of the window, and in places where the bacillus has the best opportunity to find a favorable soil for its propagation. Kissing must be interdicted, as the bacillus may be deposited upon the lips and face, thus eventually finding access to the system.

Bovine tuberculosis when occurring in our Vermont herds is never noticed by the law, as is pleuro-pneumonia, but only by the farmer when he observes that a certain animal "is not doing well," is "off its feed," or "running down." What is his course in such a case? Invariably the animal is "stuffed" and given only limited exercise until sufficiently presentable either to sell to the butcher, or to slaughter at home, the meat being peddled (in the majority of cases by wholly innocent farmers) to unsuspecting consumers. The farmer will not allow any stock to "run-down" on his hands if he can prevent it: and, moreover, who of the consumers is to tell whether the cervical glands were enlarged or the lungs or other viscera tuberculous, since these parts are not, as a rule, offered for sale?

It has been said that cooking will devitalize the bacilli, but this was disproved by the experiments of Professor Gerlach, who cooked meat known to be tuberculous from fifteen to thirty minutes, fed it to animals, and produced consumption in two-thirds of all those experimented upon. I have personal knowledge of certain animals with swollen cervical glands, scrofulous joints, and emaciated frames that are being milked daily, part of the milk being consumed by the family, the remainder going to cheese factories, where, according to Professor Gerlach, the degree of heat to which the milk is subjected in the cheese-making process is not sufficient to devitalize the bacillus. Then as to the milk we drink: who, in the absence of official inspection, is to tell us whether it is sound or not? Surely not the farmer, who is ignorant of the existence of this germ. It may be said that the milk can be sterilized by boiling, but here again we are doomed to disappointment, for Professor Bollinger, of Munich, has demonstrated that tuberculous milk even when boiled will produce consumption.

What abominations are sold in the form of canned goods can only be surmised, as the Government makes no provision for their supervision. But the country is waking up to the importance of this question. The Government spends $500,000 per annum in the work of exterminating pleuro-pneumonia in our herds, but not because the disease can be transmitted to man. A much larger sum could be profitably expended in the extermination of tuberculosis, for it is clear that, in many cases, this disease, which kills one-seventh of the human race, is carried to man in infected meat and milk. Not long ago, in Oregon, all the cows in a noted and valuable herd were killed, because they either had tuberculosis or had been exposed to the disease. This action of Oregon is in the right direction, and should be followed by all the States. The great remedy for tuberculosis is to instruct and urge our Board of Cattle Commissioners (who have the requisite power granted them by the statutes) to ferret out all cases of tuberculosis among our herds with a view to its extermination, just as is done with pleuro-pneumonia. And, as already mentioned, the slaughtering of all animals for food purposes should be under the supervision of a veterinary pathologist. In connection with this the methods of inspection practised by the Jews is of interest. According to Behrends:

"Kosher meat, as the passed-inspection Hebrew meat is called, is thus prepared under the inspection of the proper official, often the rabbi himself, certainly one familiar with pathological appearances. A perfectly sound and presumably healthy animal is selected and thrown, and a keen, sword-like knife, three feet long, is pushed once across the throat, and then drawn forcibly back toward the operator, the animal then being hung up by the heels until thoroughly drained of blood. That oft-quoted jugular vein is, of course, severed, and so are the large arteries, by those terrible cuts, for the knife goes to the bone. Every organ is then carefully examined for traces of disease, especial attention being paid to the lungs, which must be non-adherent to the chest or to each other in any lobe, and must be fully inflated, then cut into and examined for foci of disease. The larger veins and arteries must then be dissected from the meat, for it is along them that abscesses are usually found, if found at all. If a defect is found at any of these points the meat is rejected as unsuitable for Jewish use. Poultry and fish have to pass a rigid inspection, and there are other stringent regulations regarding the treatment and cooking of even the passed-inspection food articles."

Associating this with his above-quoted forceful exposition of the immunity from consumption of the adherents of the Jewish faith, we are impressed with the importance of this matter.

This ancient custom of the Jews must be appropriated by us for our own preservation, and to insure the perpetuity of our race.

The advocacy by the *British Medical Journal* of a wider use of goat's milk is timely, and of great importance as regards infant-feeding, especially as cow's milk in cities is seldom free from a suspicion of infection or adulteration. The goat, on the other hand, does not have, or very rarely has, tuberculosis, is easily kept, and is a vigorous and healthy animal, thriving under almost any condition, while, as physiology teaches, its milk is nearest, in its several constituent properties, to human milk, therefore the best substitute.

In conclusion, let us urge our representatives to

arouse the Government to act in this vital matter, so that as speedily as possible it shall guarantee that our meat is "Kosher."

TWO CASES OF ACROMEGALY.[1]

By J. E. GRAHAM, M.D.,
PROFESSOR OF CLINICAL MEDICINE AND MEDICAL PATHOLOGY IN THE UNIVERSITY OF TORONTO.

It has been well said that he who gives a name to a certain series of signs and symptoms not previously classified confers a benefit on science.

In 1884 Fritsche and Klebs published a long article, entitled "Ein Beitrag zur Pathologie des Riesenwuchses," in which an exhaustive description of a case is given, together with a list of similar cases published under various names.

It was not, however, until after 1886, when Marie published his first paper, and introduced the term *acromegaly*, that the attention of the profession generally was drawn to this disease. Since that time a number of cases have been reported, and some progress has been made in its etiology and pathology. I might here refer to the exhaustive article of Erb, published the *Deutsche Archiv für klinische Medicin*, 1889.

Marie[2] gives a summary of cases published up to that time. In this list are eighteen undoubted cases, four probable ones, and six which, although published as acromegaly, Marie did not consider as examples of that disease. Two cases reported on this continent were not included in this list.

A case has also been published by Drs. Holschewnikoff and von Recklinghausen.[3]

Dr. Henry Waldo,[4] of the Bristol Royal Infirmary, reported a case which was of an acute form, lasting but six months. On post-mortem examination it presented some gross brain-lesions, which were very interesting and which will be referred to subsequently. The short duration of the case, the absence of marked enlargement of the head and face, the normal size of the inferior maxilla, and the peculiar condition of the skin, all make it doubtful whether this ought to be included in the list of genuine cases, or whether it is not a trophic neurosis which Virchow would describe as a partial acromegaly.

My attention was drawn to a letter in the *Medical World*, written by a physician in Missouri, in which the description of a patient is given who is probably suffering from acromegaly.

Of the cases published on this continent, one by Dr. Wadsworth[1] appeared under the heading "A Case of Myxœdema, with Atrophy of the Optic Nerves." Marie includes this in his list of genuine examples. To my mind, the case presented many symptoms of myxœdema as well as those of acromegaly. Changes of the skin and subcutaneous tissues were described such as are found in cases of myxœdema, while the enlargement of the bones would place it under the head of acromegaly.

The second case was reported by Dr. Adler[2] to the New York County Medical Society, and appears to have been a good example of the disease as described by Marie. The striking peculiarity of the case was a widespread enlargement of the lymphatic glands. There was no distinctive sign of myxœdema present.

The third case was published by Dr. O'Connor,[3] and is also a genuine case of the affection. "An extreme infiltration of the lining membrane of the cheeks and soft palate," is described, but whether this resulted from a simple hyperplasia of the connective tissue, or from an infiltration of mucin, is not clear—possibly the latter, as the doctor thought "some purely myxœdematous symptoms were undoubtedly present."

It would thus appear that three cases have already been reported on this continent. So far as I know, the two now to be described are the fourth and fifth in the order of publication.

In August of last year Dr. Osler, who was then on a visit to Toronto, drew my attention to a case in the Toronto General Hospital, under the care of my colleague, Dr. Burritt, which Dr. Osler considered to be a case of acromegaly. The patient was afterward transferred to me.

I am, therefore, indebted to Dr. Osler, who made the first diagnosis, and to Dr. Burritt, for some of the earlier notes of the first case.

The second patient I had frequently seen, and at once considered him an example of acromegaly, after the first had been shown me.

The following notes of the first case were made partly in August, 1889, but principally in April of this year:

Case I.—G. B., aged forty years. Born in Canada. When young he suffered from severe attacks of asthma, which ceased when he was about seventeen years old. When twenty he had an attack of bronchitis, which was probably complicated by asthma. This lasted about a year, and his physician was apprehensive of tuberculosis. He,

1 Read before the Association of American Physicians, May, 1890. As this paper has already been published in the Transactions of the Association of American Physicians a word of explanation is necessary. The MS. was handed to Dr. J. Minis Hays to be given to THE NEWS, and was withheld by him until two weeks ago, when this office was notified of the fact by Dr. Graham.

2 Brain, July, 1889.

2 Ibid.

American Journal of Homœopathy, 1888.

however, recovered, and has not since been troubled with asthma. At twenty-two years of age he suffered from malaria, which continued for six months. He then lived in a miasmatic region.

From that time up to the commencement of the present illness he enjoyed good health. He was a strong, well-built, athletic man, but thinks that he worked too hard on the farm. At the age of thirty-five years he married. His wife died three years ago. He had one child that died in infancy of some intestinal trouble.

Family history: His father, a native of England, died aged seventy-five years, and for years previous to his death suffered from chronic rheumatic arthritis. His mother died at sixty-five, of an obscure disease of the bowels. He has eight brothers and two sisters, all living and healthy. He knows of no case similar to his own in the family.

When about thirty-five years old he complained of severe pains in the left side of his face, which were thought to be of neuralgic character. He had several teeth extracted, which did not, however, give him any relief. Some months after this he noticed a prominence of the left malar bone, and an enlargement of the left ramus of the inferior maxilla. The presence of the malar enlargement was brought to his attention by a physician whom he occasionally saw, and who told him that a tumor was forming on the left side of the face.

About three years ago, two years after the commencement of the pains, he noticed a general enlargement of the face, and at the same time of the hands and feet. The pains have continued without intermission for the last five years. They are of a dull aching character, and are often accompanied with dizziness and an indescribable feeling of distress in the head.

Three years ago he noticed that his sight was failing, first in the left, then in the right eye. This diminution of sight has steadily progressed up to the present time.

He has suffered much from chronic constipation, and from hæmorrhoids, which frequently bleed. His appetite has always been good. He has been in the habit of drinking large quantities of water, and has taken spirits moderately.

He has at times had polyuria, which would last for a month or so. Of late, weakness and shortness of breath are noticed after moderate exertion.

At the commencement of this illness he weighed 180 pounds. He now weighs 212 pounds, and is about five feet nine inches in height.

Present condition: Patient is pale and sallow. The face, hands, and feet are noticeably large in proportion to the rest of his body. He walks slowly and heavily, with his shoulders stooped, owing to a curvature of the spine. His face is much enlarged, and elliptical in shape. The skin of the face, of a sallow color, is loose, movable, and soft, and can be pinched up in large folds. There is no appearance anywhere of a deposit of mucin such as occurs in myxœdema.

Length of the face from the top of the forehead to the tip of the chin, 245 millimetres. Breadth between the malar prominences, 160 millimetres. The forehead is low and receding. The supra-orbital arches are very large, especially the left one. The prominence of the eyebrows gives the eyes a somewhat sunken appearance. The malar bones are much enlarged, the left one being more prominent than the right. The nose is very voluminous, but is uniformly enlarged and not pugged. The upper lip is elongated and somewhat thickened. The superior maxilla is enlarged at the upper part. The alveolar surface is about the normal size, except at the posterior part of the left side. The inferior maxilla is everywhere enlarged, and is set forward, so that there is about a third of an inch between the teeth above and below when the mouth is closed. He says that before the disease began he could bite a pin in two. He has had some teeth extracted, and others are decayed. The tongue is enlarged, and presents a red furrowed appearance. The raphe is deep, and deep furrows branch out on each side.

The enlargement and position of the inferior maxilla give to the lower part of the face a heavy appearance. The lower lip is long, thick, and protruding. The chin is long and heavy. His beard does not grow nearly so fast as before the commencement of his illness.

The ears are uniformly enlarged. The cranium does not appear much larger than normal. The neck is not much increased in circumference, measuring 410 mm.

The right lobe of the thyroid can be felt with great difficulty, but no other part of the gland.

There is a slight forward curvature of the spine in the lower cervical and upper dorsal regions, and a corresponding lordosis in the lumbar region.

The hands are broad, flat, and fleshy. On grasping his hand it feels soft, and is so large that it cannot be properly held. The right is slightly larger than the left. Part of the index finger of the right hand was lost by an accident at the age of three years. The metacarpal bones are especially lengthened. The carpal joints are much enlarged and flattened, especially those of the index and middle fingers. At the side of the metacarpal bone of the little finger there is a mass of soft tissue, but not out of proportion to the fleshy condition of the rest of the hand. The palmar lines are deep and well marked. The skin presents a yellowish appearance, and is loosely attached to the subjacent tissue. The nails are short and broad, and present transverse markings; some of them are curved, so as to be sunken in the centre and turned up at the edges.

The forearms are normal in size, measuring in circumference, midway between the wrist and elbow, right 280 mm., left 260 mm. The elbows are somewhat larger in proportion: circumference over the head of the radius when the arm is straight, right 300 mm., left 287 mm. The arms midway between the elbow and shoulder joint measure: right 315 mm., left 300 mm. The scapulæ are not enlarged.

The feet are also increased in size; he is now obliged to wear boots three sizes larger than he wore five years ago. The feet are elongated and fleshy, but not particularly flat; there is no large mass of flesh found at the side of the metatarsal bone of the little toe, as was found in Marie's cases.

The feet measure antero-posteriorly, right 257 mm., left 269 mm. Circumference of the heel and instep, right 370 mm., left 385 mm. Greatest circumference of the foot, right 310 mm., left 290 mm. From these measurements it will be seen that the feet are uniformly enlarged. The toe-nails are short and broad.

The ankles measure, right 270 mm , left 260 mm. The legs, midway between the ankle and knee, measure, right 365 mm., left 352 mm. The knee-joints are slightly enlarged. Both patellæ enlarged. The thighs, midway between the knee- and hip-joints, measure, right 535 mm., left 530 mm.

The trunk does not present such abnormal conditions as will be described in the report of my second case.

The clavicles are much thickened, especially toward the sternal ends; the scapulæ are not enlarged and the sternum is not prominent; marked dulness is found over the upper third of the sternum.

The chest measures over the nipples 1020 mm.; the abdomen over the umbilicus 930 mm.[1]

His respirations are diaphragmatic in character.

April 27. 1890. His pulse is 78; temperature normal; respiration 17. His heart is normal in size; but there is an accentuation of the second sound. The lungs are normal. There is no enlargement of the liver or spleen.

About a year ago he passed large quantities of urine, but he thinks it is now normal in quantity. The following analysis was made by Dr. Caven: Reaction strongly acid. Color normal. Specific gravity 1021. Albumin about one-seventh by measure. No sugar. Pus-cells in considerable number. Abundance of oxalate of lime crystals. No casts.

There is a chain of indurated and slightly enlarged lymphatic glands along the posterior margin of the sterno-mastoid muscle on each side. A similar condition is found in some of the glands in the posterior part of the neck. There is no evidence of any other changes in the lymphatic system.

The organs of generation are normal in size, but for the last three years he has had very little sexual feeling. A double varicocele is present.

He has a deep bass voice, which he says does not at all resemble that of five years ago. He could then sing and whistle with ease, now he cannot call out loudly, and can sing and whistle with difficulty.

The patient is much troubled by a thick mucus which collects in the back part of the mouth. There is much thickening of the mucous membrane of the posterior nares; this, in all probability, is the predisposing cause of the occasional deafness from which he suffers. His appetite is always good, and he is not often troubled by indigestion.

The tendon- and skin-reflexes are normal. Muscular power of the arms not much diminished. Last fall he had more than the ordinary strength of the forearm; at the recent examination his grasp was not so strong.

He complains of hyperæsthesia over the left side of the neck and head, also over the gums on the left side. There are no abnormal sensations in the extremities. He has a dull aching pain in the forehead, face, and teeth, from which he says he is never free.

The following account of the condition of his eyes was sent me by Dr. Reeve: Vision very imperfect; right eye, V. $= \frac{8}{CC}$: left eye, $\frac{10}{CC}$: and reads 14 Jaeger. Double temporal hemianopsia. Color-sense defective for green. Pupils of normal size and respond well to light and accommodation, but do not dilate well. Right pupil almost, if not quite, unaffected by a pencil of light from the temporal side; left pupil more influenced. Gray atrophy of optic nerves, not post-neuritic. Retinal arteries not more than one-half normal size, and veins small. Divergent strabismus. No present diplopia.

His hearing is at present fairly good; taste and smell normal.

He is not intellectually bright, and says he cannot do business as well as formerly.

He believes that he has improved during the winter months, but his appearance is not nearly so healthy as when he was last in Toronto.

The history of my second case was obtained partly from the attending physician, Dr. Leslie, and partly from the relatives of the patient. Although I had frequently seen him, I was never called to visit him professionally. He was sensitive about his condition, and did not like to have it referred to.

Case II.—Mr. T., aged fifty-seven years, bank clerk, born in Edinburgh, came to Canada when he was twenty-three years of age. Nothing was at that time noticeable about his figure. He was a strong, well-built, large-boned man, about five feet ten inches in height. Shortly after his arrival on this continent the enlargement of his head and face commenced, and at twenty-eight years of age the change was so marked that his mother, whom he then visited in Scotland, scarcely recognized him, and expressed great astonishment at his appearance.

So far as can be recollected the enlargement of the hands and feet began at the same time as that of the head. A gradual increase in the size of the extremities went on for years. Of late, the change in the form and size of the trunk was more noticeable.

During the last five years of his life he did not do any work. He had ample means, and seemed disinclined to enter into business. He was morbidly sensitive about his appearance, and did not care to talk about it, even to his physician. He was of an amiable, affectionate disposition, and spent most of his time at home. He was unusually bright and cheerful, fond of reading, and he talked with much intelligence.

The changes in the extremities may be described as follows: His hands were much enlarged, broad, and flat. The carpal joints were enlarged, so that he could not wear an ordinary finger-ring. The flatness and broadness of the hand were especially

[1] For a complete table of the measurements in this case see Transactions of the Association of American Physicians, 1890.

noticeable when he placed it with the palm downward on the table. A soft enlargement by the side of the fifth metacarpal bone could then be more especially seen.

His nails were short, broad, and small compared with the size of the fingers. He kept his nails closely cut, a circumstance which gave them a still shorter appearance. The right hand was considerably larger than the left.

His wrist was enlarged, measuring 9 inches in circumference.

There was nothing noticeable about the forearm and arm, except that during the latter years of his life they became much emaciated.

The feet were also enlarged, but not unshapely. The toes were elongated and flattened. (The sole of his slipper measured 12 inches in length by 4 in breadth.)

There was nothing noticeable about his legs and thighs, except a considerable enlargement of the knee-joints.

His head was much enlarged. Circumference, as shown by his hat-band, was 24 inches. His hat measured 8½ inches antero-posteriorly by 6½ transversely.

The face was elliptical in shape. The forehead was low and sloping. His son, who is now twenty years of age, has a similarly-shaped forehead. The eyebrows were prominent, and the skin over the forehead much wrinkled.

His nose was uniformly enlarged and slightly pugged.

His lips were thickened and enlarged, the lower being much more prominent than the upper.

The upper and lower jaws were much enlarged. He had a long, fat chin, which at ordinary times rested on his chest.

His neck, short and thick, seemed to be set on the upper and anterior part of the trunk. It was much arched behind and was marked by large, thick folds of integument, which were separated by deep furrows. His ears were also much enlarged.

His shoulders were much increased in size, and one was more forward than the other. There was a marked curvature of the spine in the upper dorsal region. The distance along the spine from the collar of the coat to a line drawn between the upper border of the axillæ, a measurement which tailors make, was 15 inches. The usual length of such a measurement is 7 or 8 inches.

The sternum was very prominent toward the upper extremity, and the ribs were flattened on each side. The circumference of the chest over the nipples measured 47½ inches.

Besides the kyphosis, there were lateral curvature and lumbar lordosis. The latter was very marked.

He at one time complained a good deal of toothache, and eleven years before his death had all his teeth removed.

His sight was good up to the day before his death, when he became almost totally blind. His hearing was acute, as were also his taste and smell.

He had a deep bass voice, which was slightly husky. He could never call out loudly, but always whistled when he wanted to attract the attention of any one at a distance. About the beginning of the year 1889 he caught cold, from which he was some time in recovering.

During the following winter months his family noticed that he slept more than usual. He would come down to breakfast, after a long night's sleep, looking pale and worn, and would fall asleep in his chair two or three times during the day. This tendency to somnolency increased during the early part of the summer.

The first time he consulted Dr. Leslie was about five years before his death. He then wished to obtain a certificate to exempt him from jury duty. He stated that he was nervous, and that he could not hear or speak well.

He afterward occasionally consulted the doctor about severe headaches from which he suffered. They were of the nature of migraine, and often lasted one or two days. He could not take much exercise, as he became easily tired. His appetite was always good, and he complained frequently of thirst. His urine was examined in January, 1889, and was found to be free from albumin and sugar.

On January 29th, he called on the doctor, complaining of pain in the calf of his right leg. He had been on his feet more than usual, and he was troubled with varicose veins. The pain was thought to be due to phlebitis. The limb afterward became red and swollen, and an abscess formed, which was lanced on July 11th. After a free discharge of pus, the patient improved until the 14th, when he became delirious. He afterward sank rapidly, and died on the 16th, apparently from acute septicæmia

Measurements:

Circumference of chest over the nipple, 1162 mm.

Circumference immediately above the crest of the ilium, 1062 mm.

Distance from the collar of the coat to a line drawn across the upper margin of the axillæ, 387 mm.

Circumference of neck, 462 mm.

Circumference of wrist, 231 mm.

Circumference of head, 612 mm.

Circumference of right-hand at metacarpo-phalangeal joints, 216 mm.

Length of index finger, 127 mm.

Length of ring finger, 136 mm.

Length of little finger, 107 mm.

Length of thumb, 105 mm.

Length of foot, 301 mm.

Breadth of sole, 110 mm.

Circumference of foot, 262 mm.

These measurements are not quite accurate, as they were made from the patient's clothing.

In the cases just described remarkably similar signs and symptoms were present.

The differences will first be noted:

In the first case there was loss of sight from optic neuritis, a condition not present in the second. The latter patient appeared to be in a more advanced stage of the disease, as shown by the changes in the spine and thorax—changes which became more pronounced in the last five years, and which

were present to only a limited degree in the first patient. The disease began at an earlier age in the second case and lasted twenty-three years. In the first it began at thirty-five, and from present appearances he will not live as long. Albumin was found in the urine of the first and not in that of the second case.

In each case there was a marked increase in the size both of the face and the extremities, and this enlargement was due not only to involvement of the soft parts, but of the skeleton as well. In neither case was there any myxœdematous condition of the skin or subcutaneous tissue.

The face in each case was elliptical, the cheek bones were prominent, the superior and inferior maxillæ were enlarged, the lips were thickened—the lower one more than the upper. The upper alveolar process in the second patient was much more enlarged than in the first.

In each patient the hands were increased in size and there was marked enlargement of the carpal joints. There were enlargement and lengthening of many of the bones and an increase of the connective tissue. The same description will apply to the feet.

In each case there was gradual lessening of vitality, although the mental faculties remained, to a great extent, unimpaired. In the second patient this diminution of vital force was more marked during the last six months of his life.

Each patient suffered from severe aching pains about the face and head. The first patient was a plain farmer of fair education, whereas the second was a well-educated man.

There can be little doubt that both cases belong to that class described by Marie under the name of acromegaly. That they were not cases of myxœdema is evident from the following facts:

1. The dimensions of the bony skeleton were in many parts much increased, whereas in myxœdema the soft parts are alone affected.

2. The face in myxœdema presents a round, full-moon appearance. In each of these cases the face was elliptical.

3. In myxœdema there is a distinct waxy-like condition of the skin and subcutaneous cellular tissue. There is also a thickened and scaly condition of the integument. In neither of the cases described was there thickening of the skin, and only in the first was there any discoloration.

4. In neither case was the mental condition present which is so marked in myxœdema. The first patient is engaged in selling horses, a business which cannot be carried on without a good deal of shrewdness.

The osteitis deformans of Paget is excluded, as in that disease the head is enlarged and the face retains almost its normal size. In the cases described the enlargement existed principally in the face. The deformities of the long bones which exist in osteitis deformans were not found in these cases. The latter disease begins after the age of forty years, while in the histories narrated the disease began earlier in life. There was more symmetry in the enlargement of the bones in the cases described than there is in osteitis deformans.

In gigantism we have a condition in which the extremities are enlarged only in proportion to the general stature. The face is not elongated and the lower jaw is not hypertrophied, or set forward, as has been described.

The leontiasis ossea of Virchow is excluded, as in these cases there were no well-defined bony tumors, but there was hypertrophy of the hands and feet—a condition not found in the disease described by Virchow.

Marie, I think, properly excludes localized hypertrophies, such as that of one extremity, or unilateral hypertrophy of the face, from cases of this affection.

It is possible that these dystrophies may be produced by localized lesions of trophic centres similar to the general lesion which may hereafter be found in acromegaly; such, for instance, as has been found in von Recklinghausen's case. In the case just described, as well as in the twenty-two reported by others, there is a distinct clinical history, as well as pathological conditions, which separate them from all previously described diseases.

Although, in my opinion, there is little doubt of the existence of acromegaly as a distinct disease, it seems, in some cases, to have a close relationship to myxœdema. For instance, in Wadsworth's case, which is put in the list of genuine examples by Marie, there was a waxy condition of the skin, as well as an enlargement of many of the bones of the skeleton. The same condition is described in the report of Tresilian's case. From this it would appear that, although in most cases of acromegaly the skin simply undergoes the same hypertrophy as the subjacent soft tissues, there are cases in which a myxœdematous condition is found in addition to the hypertrophy of bones and soft parts.

In studying the possible connection between these two affections two sources of error must be guarded against. Cases may have been described in which the skin and subjacent tissues were myxœdematous, and in those cases the waxy condition was not really due to a deposit of mucin. Again, as Virchow suggests, in cases of genuine myxœdema the bones may be enlarged to a considerable extent without the enlargement being noticed, because of the thick covering of integument and connective tissue infiltrated by mucin.

On account of the small number of post-mortem examinations made in cases of acromegaly, there is

much obscurity as to the true nature of the affection. I regret very much that in this respect the report of my second case is so defective.

In one of Marie's cases Broca described the changes in the skeleton as follows: "The spongy tissue is especially the seat of hypertrophic changes, so that the following statement may be considered as representing the reality: In the skeleton of acromegaly hypertrophy shows itself in the bones of the extremities and in the extremities of the bones."

With regard to the morbid anatomy, Marie comes to the following conclusions: "Until proof to the contrary is brought forward, I shall cling to the belief that these three anatomo-pathological characters manifest themselves not only with a remarkable degree of frequency, but may even be looked upon as constant, viz., hypertrophy of the pituitary body with enormous dilatation of the sella Turcica, persistence of the thymus, and hypertrophy of the cord and the ganglia of the sympathetic system."

Klebs mentions prominently the enlargement of both the veins and arteries, and particularly the increase in the size of the valves in the veins. In some cases the thyroid gland has been either atrophied or diseased, whereas in others it has been found normal.

Since the publication of Marie's paper, in which the foregoing statement appeared, the few autopsies made have been on cases of doubtful diagnosis. The case described by Holschewnikoff and von Recklinghausen, previously referred to, presents some points of great interest. The patient died shortly after admission into the hospital, and the clinical history is, in consequence, defective. The autopsy was made in 1886, before Marie had published his first paper.

The measurements, with the exception of those of one hand, were not made in detail, nor was the appearance of the head and face elaborately given. The case is described as one of "syringomyelia and peculiar degeneration of the peripheral nerves, combined with trophic disturbance (acromegaly)." It presented the peripheral and central lesions of syringomyelia, together with the peculiar enlargement of the bones found in acromegaly.

The study of this case would direct one's attention to the spinal cord as the probable seat of the primary lesion in acromegaly. Unfortunately, as von Recklinghausen states, the spinal cord has not been carefully examined in any of the autopsies so far reported, and until such examination has been made much doubt will surround the pathology of this affection.

In the case reported by Dr. Waldo, and already referred to, the patient was fifty-four years of age, and the disease had lasted six months. The post-mortem examination revealed cavities in the brain, the probable result of embolism. There was also valvular disease of the heart. The condition of the spinal cord could not be stated.

In this case endocarditis, rheumatism, and embolism appeared in combination with hypertrophy of the bones and soft parts of the extremities.

From the comparatively slight opportunities the writer has had for the study of this affection, he is inclined to agree with Marie that acromegaly is a general disease presenting sharply-defined features which separate it from other pathological conditions. It would be difficult to find two cases of any chronic affection which present greater similarity of symptoms than those just described.

A point of importance in etiology might be here mentioned. Virchow, in referring to the connection said by some authorities to exist between this disease and the development of the organs of generation, gives it as his opinion that there is no evidence of any special relationship between them. It will be noticed on reading over the histories already published, that in the male there are frequently sexual weakness and even impotence, and that in the female a cessation of the menstrual function follows shortly after the commencement of the disease.

In the first of my cases there was a distinct loss of sexual feeling after the second year, while in each case the disease began shortly after marriage. In both instances, again, children were begotten while the disease was in progress.

In the first case no form of treatment proved of any avail. The second did not receive any special medication for the disease.

THE NERVE-SUPPLY OF THE SENSE OF TASTE.

By JOHN FERGUSON, M.A., M.D., L.R.C.P.,
DEMONSTRATOR OF ANATOMY IN THE UNIVERSITY OF TORONTO.

Probably few questions have been more discussed and disputed than that of the nerve-supply of the sense of taste. It is an interesting if not instructive task to look over the matter that has been written upon the subject. During the past ten years much good work has been done, but much still remains to be cleared up. It is quite generally admitted that the lingual branch of the fifth nerve and the gustatory branches of the glosso-pharyngeal carry the nerve-fibres of taste to the tongue and palate. The question, however, that for a long time hung in dispute was whether these nerves were the real supply to the parts of taste, or whether they carried nerve-fibres from some other source. It is to aid in clearing up this doubt that this contribution is offered.

One of my patients had complete loss of taste on the left side of his tongue extending to the tip. This condition had lasted two years. The most

carefully conducted tests with bitter, sweet, acid, and saline solutions and with electricity failed to elicit the slightest existence of taste on the left side of the tongue.

The posterior part of the tongue, the fauces, and palate retained the power of taste, and a ready distinction could be made between sweetness and sourness. The region of the circumvallate papillæ could detect the metallic taste of a galvanic current from two cells.

I informed my patient of the great interest that centred in the case, and he agreed to permit an autopsy upon himself if he should die within my reach. As he had phthisis with cavities in the lungs the opportunity for a post-mortem examination did not seem very remote, nor did it prove so.

The autopsy revealed a small exostosis in the scaphoid fossa pressing upon the posterior opening of the Vidian canal, and by pressure destroying the Vidian nerve. The nerve-degeneration following this pressure could be traced along the main course of the Vidian, and thence along its two branches, the carotid and the petrosus major. This latter enters the geniculate ganglion of the facial. The degeneration could be readily followed until the point was reached at which the chorda tympani is given off. The process of degeneration here left the facial and followed the chorda tympani throughout its length. This condition of secondary degeneration was traced from the chorda tympani to the lingual branch of the third division of the fifth nerve, and thence along the lingual.

In the above case we have complete proof that the nerve-supply of taste for the tip and anterior part of the sides of the tongue comes from the fifth nerve, and enters the superior maxillary division of the same nerve. The course must then be from the superior maxillary nerve into the spheno-palatine ganglion, thence by the Vidian, through the Vidian canal to the gangliform enlargement of the facial, along this to the chorda tympani, through the chorda tympani into either the lingual, a branch of the third, or inferior maxillary of the fifth.

It will also be seen that the Vidian is not a motor root passing from the facial to the spheno-palatine ganglion, but a sensory nerve of the special sense of taste passing from the spheno-palatine ganglion of the second division of the fifth nerve to the seventh or facial.

Another important deduction from a study of this case is that the nerve fibres of taste for the back of the tongue, the fauces, and the soft palate cannot be carried by the chorda tympani; for although the chorda tympani was degenerated, yet the taste, as stated, was retained over the posterior part of the tongue, the fauces, and palate.

In cases, then, of disease in the middle ear, causing loss of taste on one side of the posterior part as well as of the tip and sides of the tongue, we must look for some other explanation than disease of the chorda tympani. For the elucidation of this problem I submit the following case:

It is that of a young man who has had otitis media, with caries, for about ten years, caused by an attack of scarlatina. On making the most careful examination as to the condition of taste, it became evident that there was complete hemiagensia.

Now, the only nerves that could have been involved in this case were those of the middle ear, the chorda tympani, and the tympanic plexus. The first case clearly proves that loss of taste in the back of the tongue and palate is not due to destruction of the chorda tympani, and therefore it must be due to disease of the tympanic plexus.

Now it is known that complete destruction of the root of the fifth nerve destroys the sense of taste on the side involved. We have already traced the course from the fifth nerve to the tip and side of the tongue, and it remains to trace the course from the fifth to the back of the tongue and palate.

The chorda tympani has been excluded as not having any part in the sense of taste of the back of the tongue and palate; and yet disease of the middle ear may destroy taste in these parts. Returning to the fifth nerve for a moment, we can trace the course as follows: From the main root into the inferior maxillary or third division, from this to the otic ganglion, and then by the small petrosal to the intumescentia of the facial, then into the tympanic plexus, and finally through this plexus to the glosso-pharyngeal, and back of the tongue and palate.

Disease of the root of the fifth nerve causes loss of taste. The channels by which the root of the fifth nerve can become connected with the middle ear are the Vidian nerve and its branch, the great petrosal from the spheno-palatine ganglion, and the small petrosal from the otic ganglion. Disease in the middle ear, like disease of the root of the fifth nerve, may cause total hemiageusia. And thus it is that middle-ear caries must destroy the taste-path of the great and small petrosal nerves. Following the course from the middle ear we notice that the tympanic plexus is connected with the glosso-pharyngeal, and through this with the back of the tongue and palate. The connection of the tympanic plexus with the glosso-pharyngeal nerve is established by the tympanic branch that joins the petrous ganglion of the glosso-pharyngeal.

But this is not all the evidence that can be submitted to prove that the sense of taste must come from the fifth nerve. In another case bearing upon this question there was every reason to believe that there was pressure of syphilitic origin on the left side of the medulla. The paralysis of the glosso-pharyngeal, spinal accessory, and vagus on the side of the disease, together with paralysis on the opposite

side of the body, was extreme. Now if the glosso-pharyngeal nerve contained at its origin fibres of the special sense of taste, this would have been lost, which was not the case. Indeed, the sense of taste over the back of the tongue and palate was quite good. Here we have conclusive proof that the root of the glosso-pharyngeal nerve does not contain any fibres of the special sense of taste.

The route for the sense of taste, so far as the glosso-pharyngeal is concerned, would be from the root of the fifth to the third division of the fifth, then to the otic ganglion, from this by the small petrosal to the ganglion on the seventh, thence to the tympanic plexus, again by the tympanic branch to the petrous ganglion of the glosso-pharyngeal, and by this latter to the back of the tongue, fauces, and palate.

RUPTURE OF THE VAGINA AND ESCAPE OF THE FŒTUS AND PLACENTA INTO THE PERITONEAL CAVITY.

By GEORGE B. TAYLOR, M.D.,
of Barclay, Pa.

The patient, Mrs. S. J., was thirty-nine years old and born in Ireland. Her previous pregnancies were normal and the labors moderately easy.

When first seen by the writer she had been in labor twelve hours, under the care of her mother and a friend. Her pains were short and frequent and caused much suffering, "but were not the right kind." The woman was enormously fat, the pendulous abdomen almost resting upon the thighs when in the sitting position. Thus far during the labor she had been either sitting, leaning forward in a chair, or kneeling by the bedside to increase the pains.

External examination showed an umbilical hernia, the capacity of the sac probably being about one quart. The abdominal walls were lax and contained a large amount of subcutaneous fat. The uterus was anteverted to such a degree that with the woman erect its axis was approximately horizontal and with the fundus directed obliquely to the right. When upon her back this obliquity was increased. The vagina was unusually capacious and relaxed, especially in the upper portion. The pelvis was wide and roomy. Two fingers in the vagina were just able to reach the presenting part of the child. The cervix was dilated to about the size of a silver dollar and its margin was rather thick, fleshy, and soft. The membranes had ruptured and the head, with the encircling cervix, was resting on the pubic bone. Nearly one-half the area of the presenting part was inaccessible to the exploring fingers, and was in front of and above the pubes. The position, not positively determined, was probably left occipito-anterior.

After endeavoring to replace the womb in its proper position, with somewhat doubtful success, owing to the thickness of the abdominal walls, and directing the woman to remain upon her back, I was called from the room and detained about fifteen minutes. On my return I found the patient on her knees again by the side of the bed. I insisted on her immediate return to bed; objecting to this, as she said her pains were getting stronger since she arose, she unwillingly and clumsily climbed upon the bed, and while upon her hands and knees was seized with a severe pain, almost immediately followed by a second of still greater severity and longer duration. During the latter part of this pain she assumed a position on her knees and elbows, with her face buried in the pillow—in fact, almost the knee-chest position. The pain suddenly ceased with the sensation of "something giving way," but there were no evidences of shock or anything to indicate what had actually occurred.

During the preparation for another vaginal examination she had continuous, slight, colicky pain about the umbilicus, with one or two, not severe, uterine pains. With two fingers in the vagina the os could not be reached. Passing in the entire hand the uterus was found well contracted and entirely empty, as after the completion of an ordinary labor. The aperture of the os was transverse with a shallow notch on the right side. Passing behind the cervix the finger-tips came in contact with the smooth peritoneal covering of the sacral prominence. There was a large rent in the vagina passing posteriorly half-way to the vulva, and anteriorly to the cervico-vaginal junction and gaping widely at the sides. The rent gave the impression that the tissues had parted transversely across the vaginal vault and then longitudinally in or near the median line toward the vulva. The rectum was empty. Baring the arm to the shoulder the hand was passed behind the uterus into the abdominal cavity. The intestines were flaccid with little or no distention. The feet of the child were found beneath the spleen, the head lying in the left inguinal region, in front of and facing the left uterine appendages. The feet were brought down by traction and the head elevated by external manipulation, and delivery by the feet was accomplished with little difficulty. The child—dead, of course—weighed twelve pounds. The cord was cut and followed into the abdominal cavity up to the fundus and over and in front of the uterus. The placenta was beyond the reach of the hand and where the head of the child had been, from whence it was lifted by means of the cord and remove through the vagina.

The vagina was irrigated with a 1-to-40 carbolic solution. A long tube was inserted into the peritoneal cavity, and a stream of boiled water passed through it. No clots were found, and the amount of blood lost was trifling—probably not more than two ounces. Antiseptic precautions were used as far as possible before and after delivery, the surroundings and attendance being such as to render them for the most part futile.

It should be stated that there was no other physician nearer than seven miles, and that the case occurred on a cold winter night. Hence, I delivered the woman without professional counsel. Dr. Ladd, of Towanda, saw the patient in consultation twelve hours after delivery, and by digital examination found the condition of the vagina, etc.,

as stated above. After delivery the temperature gradually rose, reaching 102° on the second day, but in the next twenty-four hours falling to nearly normal, where it remained. The pulse (100 one hour after delivery) never regained its normal rate or character, and progressively lost force and volume until the seventh day, when the patient began to have "fainting spells," or "weak spells," in one of which on the tenth day after delivery she died. These attacks were probably cardiac dyspnœa, and death was doubtless due to heart-failure from afebrile sepsis.

During the extraction of the child the surface of the uterus, so far as accessible, seemed perfectly normal, the only uterine injury noted being the slight laceration or notch on the right side of the os.

No force was used by the manipulating hand—an old laceration of the perineum, the relaxation of the soft parts, the size of the pelvis, and the extent of the vaginal laceration furnishing plenty of space. There was at no time prolapse of the intestines.

Remarks.—The cause of the accident in this case depended on no one condition, but upon a combination of circumstances, the chief and immediate determining factor being the posture assumed at the time the child was expelled from the womb. The favoring conditions, more or less dependent upon one another, were the non-engagement of the head and its lodgement at the brim, uterine anteversion, looseness of uterine attachments, relaxation of the vaginal walls, pendulous abdomen, and gravity acting upon the uterus and its contents.

It might be here noted that the "functional lordosis," produced by obesity, must be a powerful factor in causing and maintaining anteversion of the pregnant uterus, and, as in this case, the projecting lumbar spine may have some influence in directing the whole organ forward, and lodging the head and cervix upon the pubic bone.

During the interval between the first examination and the patient's return to bed the stronger pains no doubt rapidly dilated and retracted the os, and gravity still further tilted the fundus anteriorly, producing by flexure over the pubic bone a narrowing of the antero-posterior vaginal diameter and longitudinal tension of the posterior vaginal wall. The head, fixed on the pubes, could not advance, and, as the os still further retracted, the tension and flexure became more pronounced. In labor, as the head passes from the os uteri, it may by flexion be directed to the pelvic inlet, and there engage, or if the flexion is antero-lateral it may pass around the brim to the iliac fossa. The resultant line of the expulsive and resistant forces falling within the circumference of the superior strait determines the first event in normal labor. In the present case this resultant was directed externally to the circumference, and this with the inclination of the fundus toward the right, directed the head toward the iliac plane, backward, outward, and to the left, at the same time causing antero-lateral flexion of the head, and forcing it along the iliac plane toward the outer border. The head then burst through the inelastic friable walls of the vagina, when, free from resistance, aided by gravity, and impelled by the uterine forces, the child underwent spontaneous version, and slipped without hindrance into the peritoneal cavity. Or, it is not impossible that the vaginal wound was produced by the retraction of the cervix over the head, the head then passing into the iliac fossa, the shoulders emerging from the uterus, the anterior one being caught on the inner border of the pelvic brim, until at last, in the height of a pain, and when the woman dropped her head into the pillows, the uterus passed along the anterior abdominal wall toward the chest, released the shoulder, and was immediately emptied by the powerful pain. The sensation of something giving way undoubtedly occurred at the time the child passed into the peritoneal cavity. The afterbirth was probably expelled by one or two slight pains, which occurred during the resumption of the dorsal position. The positions of the child and placenta in the abdomen, as described, occurred while the patient was placing herself upon her back after the rupture.

This case has been reported at some length, for the reason that several of the writer's local professional friends seemed disposed to doubt the possibility of such an accident, and explained the case as one of rupture of the uterine neck and lower segment, extending to the vagina. The case occurred three years ago, in the second year of the writer's practice, and inasmuch as both previously and subsequently to this incident his obstetrical practice considerably exceeded that of the average general practitioner, he feels justified in believing his observations of the case correct, and in asserting that the above is not only a possible but a probable mechanism in such cases. Moreover, medical literature affords indubitable evidence that rupture of the vagina, with escape of the fœtus into the abdomen, has occurred in labor at full term.

It might be added that this case is analogous to rupture of the uterus as usually occurring, substituting the dilated os for the contraction-ring, and the upper portion of the vagina for the thinned and stretching lower segment. The various obstacles which cause a uterine tear are here represented mainly by the impingement of the head upon the brim.

The New York Polyclinic.—The curators of the New York Polyclinic announce that hereafter they will refuse to matriculate all persons who have not been graduated by some recognized medical college, or who have not obtained a legal permit to practise medicine, after two full years at such college.

INFANTILE VULVAR HÆMORRHAGE.[1]

By THOMAS E. Mc ARDLE, A.M., M.D.,
of Washington, D. C.

In the present report it is my purpose to place on record two cases of infantile vulvar hæmorrhage. Comparatively few cases are mentioned in general or special medical literature, and the text-books are almost completely silent upon the subject. I would have been surprised, not to say alarmed, when my attention was called to my first patient, if the subject had not been made familiar to me by a recent case in the practice of a medical friend.

Each of the few medical writers who have reported cases has offered a different theory of the cause. I have no theory at all to advance, and have only to say in regard to some of the explanations of this phenomenon that hæmorrhage from the infantile male genitalia would be as frequent as from the female if the theories were correct. We know, however, that rare as the phenomenon is in the female, it is much less frequent in the male infant.

Case I.—On September 25, 1889, at 2 o'clock in the morning, I delivered Mrs. T. of her fifth baby, a girl. At my visit on the morning of September 30th, the nurse informed me that the infant had passed blood with every movement of the bowels since the preceding morning, and I was shown five napkins which were considerably stained with blood. I immediately examined the child and discovered that the hæmorrhage came from the vagina, and not from the bowels. At the time of the examination there was about a half-teaspoonful of blood in the vagina and between the labia. This blood was bright-red, and the napkin was stained by it, showing that the flow was continuous. The anus was perfectly clean and healthy.

Borated absorbent cotton was ordered to be used and perfect cleanliness enjoined. At the end of the fourth day the hæmorrhage ceased, and the child has since continued perfectly well.

Case II.—On April 10, 1890, I delivered Mrs. C. T. of her first child, a girl. The labor was tedious, but in other respects normal. Five days later, at the morning bath, blood was discovered coming from the vagina of the infant. The same treatment was adopted as in the preceding case, and in four days the hæmorrhage ceased.

It will be observed that in each infant the hæmorrhage occurred on the fifth day after birth, lasted four days, and did not return.

The blood came from beyond the hymen and trickled between the labia. Whether it came from the vagina or uterus I am, of course, unable to state with any degree of accuracy, but it is my opinion that it came from the uterus. There was no malformation discoverable in either case. Both are bright and happy babies, perfectly well nourished, and have passed through their first summer without any difficulty.

[1] Read before the American Association of Obstetricians and Gynecologists, September, 1890.

MEDICAL PROGRESS.

Intubation of the Larynx in Croup.—D'Heilly (*Archiv f. Kinderheilkunde*) reports thirteen cases of intubation for croup, the symptoms being such as usually require tracheotomy, namely, persistent dyspnœa, recession of the epigastrium, and commencing asphyxia. The youngest child was nineteen months old, the oldest four years. Two of the children were too near death to be benefited by any treatment; of the remaining eleven, only two were saved. In spite of this high mortality the author formed a favorable opinion as to the value of the procedure. It involves no loss of blood and no wound, it can be carried out easily, and serious and unexpected accidents are not likely to occur. An unsuccessful intubation can be repeated, and, if continually unsuccessful, tracheotomy can be performed. Neither shock nor rise of temperature attends the operation, and the air is not cold when it reaches the lung as it is when inspired through a tracheotomy tube.

On the other hand, the tube is frequently obstructed by false membrane, when it must be quickly removed and as quickly reintroduced. American authors recommend that the patient be allowed to cough the tube out, but this was never observed in d'Heilly's cases. Another objection to intubation is the difficulty of swallowing that it produces, which of necessity interferes with nutrition. Especially is this difficulty experienced in the administration of liquid food, which may be inspired and cause pulmonary disease. Feeding through the nose by means of a catheter may obviate this difficulty, but is attended with others.

The author thus summarizes the conditions in which the method may be used:

1. In very young children in whom tracheotomy offers only slight chances of recovery, and in whom even a slight loss of blood would be harmful.

2. In mild cases of croup which seem likely to continue as such and for which tracheotomy is a severe remedy.

3. In very severe cases of toxic diphtheria in which the patient is already much weakened.

4. In cases of croup following measles, in which tracheotomy is never successful. Intubation in such cases offers a slight chance of success.

5. In all cases in which tracheotomy is impossible or dangerous.—*Archives of Pediatrics*, October, 1890.

Treatment of Profuse Menstruation.—The following prescription for the treatment of profuse menstruation is quoted by the *Southern Practitioner*:

℞.—Dialyzed ergot	. . .	10 drachms.
Glycerin	. . . .	5
Salicylic acid	. . .	30 grains.
Distilled water	. . .	2½ ounces.—M.

One teaspoonful of this should be diluted with three teaspoonfuls of water, and injected into the rectum once daily.

The Treatment of Alopecia Areata.—This malady, which is probably due to the presence of the parasite, microsporon Audouini, is treated in the following manner by Quinquand:

The general treatment consists in the employment of cod-liver oil for three or four weeks, and after this the administration of from 5 to 6 drops of Fowler's solution daily. The local treatment consists in washing the parts thoroughly with soap, and immediately after applying to the affected surface the following mercurial solution:

R.—Biniodide of mercury . . 3 grains.
Bichloride of mercury . . 15 "
Alcohol . . . . 1½ ounces.
Water . . . . . 8 ounces.—M.

Following this, friction is to be made with the following liniment:

R.—Balsam of Fioravent, Camphorated spirit, of each 4 ounces.
Tincture of nux vomica . 1½ drachms.—M.

Mixture for the Treatment of Myringitis.—

R.—Crystallized acetate of lead . 1½ grain.
Tincture of opium . . 20 drops.
Distilled water . . . 10 ounces.—M.

Make into a solution, and three times a day drop 10 minims into the ear. If this produces a considerable exudate in any portion of the tympanic membrane, it should be followed three times a day by 5 drops of pure glycerin, and syringing with warm water.

Multiple Abscesses in Nursing-infants.—According to Couder, Bouchut was the first to make a study of this disease, and he believed it to be due either to conditions of the puerperal state, to syphilis, or to scrofula. Syphilitic abscesses should be regarded as merely softened gummata, and scrofulous abscesses are usually of tubercular origin. Couder cannot believe that all other cases are attributable to the puerperal state, and considers that there are others of unknown origin. Among the latter cases should be included those in which the mothers of the patients suffer from inflammation of the milk-ducts, pus being withdrawn by the infant in the act of nursing. Such cases may be considered instances of benign purulent infection, and the condition is an indication for withholding the breast from the child.

Abscess may also occur through infection of the umbilicus, hence in all cases the infant's umbilicus as well as the mother's breasts should be treated antiseptically.—*Archives of Pædiatrics*, October, 1890.

Antisepsis in Obstetric Practice.—In the Section of Obstetrics of the recent International Congress, a paper by Dr. Galabin, upon the use of antiseptics in midwifery was read. The excellent results of antisepsis in obstetric practice are ascribed by this author chiefly to the use of corrosive sublimate as a disinfectant for the hands, and for the purpose of irrigating the vagina both before and after labor. The rate of mortality in English maternities since the introduction of corrosive sublimate has fallen from 10 per 1000, to 2 per 1000. In the London General Maternity the patients are confined on horsehair mattresses that are disinfected if the case should become septic. For vaginal irrigation a 1-to-2000 sublimate solution is used for two or three days, and after that a weaker solution. Before an examination, the hands are disinfected with a 1-to-1000 sublimate solution and lubricated with a 1-to-1000 solution of sublimate in glycerin. In normal cases in private practice he thinks a single injection of 1-to-2000 sublimate solution sufficient.

Slawjanski, of St. Petersburg, said that in Russian maternities antisepsis is universally employed and has reduced maternal mortality to 0.28 per cent., and that if the method is properly carried out the presence of students has no effect upon the mortality.

Priestly, of London, ascribed the good results of antisepsis in obstetric practice less to the antiseptics used than to the extreme cleanliness. He believed that sublimate solutions as weak as even 1-to-4000 could produce harmful effects.—*American Journal of Obstetrics*, September 1890.

Curetting the Uterus for Endometritis.—The operation of curetting the uterus for endometritis has been performed by Bouilly seventy-five times since 1887. The procedure is particularly adapted to cases which are uncomplicated by polypi or myomata, and it may also be used in cases in which there is a certain amount of disease of the uterine adnexa. The principal indications for the operation are hæmorrhage, leucorrhœa, and pelvic and sacral pain before or during menstruation. Pain alone is not, however, a sufficient indication. In twelve of Bouilly's cases the operation was done without an anæsthetic, but such a plan is not usually advisable. Dilatation by means of laminaria tents should precede the operation for forty-eight hours. Before curetting, the vagina should be irrigated and the uterus drawn downward. If the endometritis is purulent the operation should be followed by an intra-uterine application of tincture of iodine or of carbolized glycerin; if it is hæmorrhagic, chloride of zinc should be used. For a few days subsequently the vagina should be kept tamponed with some antiseptic material.

No accidents followed any of the author's operations, and in many of the cases the pain ceased at once or soon after. If there is extensive tubal disease no benefit can be expected from the operation.—*Annals of Gynecology and Pædiatry*, September, 1890.

Prophylaxis of Acute Rheumatism.—Hirsch (*Centralblatt für klinische Medicin*, September 13, 1890) believes that to prevent recurrences of acute rheumatism it is frequently necessary for the patient to change his residence. It has been observed that the disease is especially likely to occur in certain houses or groups of houses, a fact that is strongly suggestive of the specific nature of the disease.

Injections for the Relief of Labor-pains.—In the *Revue Général de Clinique et de Thérapeutique*, September 3, 1890, the following prescription is given for this purpose, it having given satisfaction in the hands of Bousquet, of Marseilles:

R.—Antipyrin . . . 75 grains.
Hydrochlorate of cocaine 1½ "
Distilled water . . 5 drachms.

This is to be injected into the vagina in the earlier stages of labor.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to The Medical News will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author.

Address the Editor: H. A. HARE, M.D.,
1004 Walnut Street,
Philadelphia.

Subscription Price, including Postage.

Per Annum, in Advance . . . . . $4.00.
Single Copies . . . . . 10 cents.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos 706 & 708 Sansom Street,
Philadelphia.

TETANUS.

Excluding the older ideas of tetanus, those of the existence of a condition of toxæmia or of an organic nervous derangement, the first valuable suggestion as to the real nature of the disease was published by Carle and Rattone in 1884. In this instance a patient, becoming affected with tetanus from a small acne-pustule, died in the hospital of St. Maurice, in Turin, three days after the inception of the disease. Two hours after his death, the experimenters removed under antiseptic precautions the pustule with the inflammatory zone about it, and suspended it in sterilized water. This solution they injected into the cellular tissue about the sciatic nerve in rabbits, and failed to produce the symptoms of the disease in only one out of twenty-four instances. The blood from the same individual injected into other rabbits did not transmit the disease; and the rabbits in control-experiments, inoculated with septic materials from other cases, presented no tetaniform phenomena.

In the same year Nicolaïer published the results of a series of experiments which aroused considerable interest in the scientific world. In the course of a number of experiments of another nature this investigator succeeded in obtaining an experimental form of tetanus; and after a long series of further experiments, advanced the theory of its infectious nature, and described a specific microörganism—a bacillus.

Retaining in view the fact that an infectious disease should, under favoring circumstances, present an endemic and epidemic character, and the capability of transmission from one organism to another, MM. Verhoogen and Baert have recently published an article upon the nature and etiology of tetanus, addressed to the Royal Society of the Medical and Natural Sciences of Brussels. These authors cite the well-known endemic character of the disease in our Southern States, Cuba, Ceylon, a number of the Pacific islands, and in other localities, and quote a large number of circumstances that suggest the occasional epidemicity of the affection as met in man and some of the lower animals. Among a number of clinical and experimental occurrences suggesting the probability of the transmissibility of the malady, and the likelihood of the agent of transmission existing in unclean instruments, Thiriar's experience is narrated. This operator was unfortunate enough to lose ten cases of major operations by tetanus before he determined the seat of the infection to exist in his hæmostatic forceps, the thorough sterilization of which by a high temperature was happily followed by a complete cessation of the undesirable sequences.

The coincidence of tetanus with such infectious diseases as scarlet fever, erysipelas, pneumonia, or malaria, is suggestive of its similar character.

The general course of the disease; the indefinite symptoms preceding its outburst and covering the probable period of incubation; the elevation of temperature; the occurrence of epistaxis; the existence in many cases of a cutaneous eruption resembling that of erysipelas; the nephritic symptoms and renal changes; and the enlargement of the spleen, are all characteristics of the usual course of an infectious disease.

To prove the specific nature of a malady, two series of conditions must be established: first, that the infectious agent be found in the affected organism, that its presence alone, introduced either directly or after previous cultivation, gives rise to the disease and to no other form of infection, and that no other morbific agent may induce the same result; second, that in whatever different forms the disease may present itself, these differences must constitute but secondary phases, and there must always exist a simple and unique type.

Several investigators have claimed as specific to tetanus the germs of their own discovery; but it seems probable that the bacillus first described by Nicoläier should be regarded as best fulfilling the required *rôle*. This bacterium measures three micromillimetres in length and one in diameter, presents a terminal elliptical spore, is anaërobic, and, under certain circumstances of growth and temperature, possesses rotary motility.

In connection with this subject of the specific cause of the disease should be mentioned the occurrence in the tissues and fluids of the bodies of those dead from tetanus and in the cultures of Nicoläier's bacillus of several forms of toxines, isolated and described by Brieger under the names of tetanine, tetanotoxine, and spasmotoxine, alkaloids having the power to induce tetaniform symptoms when injected in animals. Such a discovery associated with the inability to obtain cultures of the bacillus from parts of the body other than the immediate vicinity of the infected wound, make it probable that the action of the germ is entirely local so far as its life-functions are concerned, although by the elaboration of these alkaloids its further influence is the general one seen in the phenomena of the affection. Such a conclusion is, perhaps, as yet unwarranted, since the absolute proof of the specificity of Nicoläier's germ is thus far wanting. That it exists in various tetanogenous substances, as the pus of the tetanic focus, and in virulent dust, is amply proved; although, on account of its anaërobic character and other special properties of growth, it is somewhat difficult to obtain in a state of purity. Obtained in such condition, it is a matter of fact, proved by a number of successful inoculations, that it possesses the power of producing the disease.

This same power is, however, claimed for several other microörganisms, although no absolute proof in these latter instances has entirely excluded the presence of Nicoläier's germ from the microbes experimented with, and there are on record numerous inoculations with Nicoläier's bacillus that failed to produce the disease. That such failures should exist, is not, however, unexpected. The complex conditions of growth, and the exclusion of air from the focus of inoculation, necessarily render a large proportion of the attempts unsuccessful. Intravascular inoculations would be apt to fail from the free access of oxygen in the blood, and the consequent destruction of the germs; free hæmorrhage from the point of inoculation would likewise tend to prevent success, and the failure to exclude the air by the rapid formation of lymph about the focus could be expected to lead to no results.

The frequent association in one focus of pus-forming bacteria with the bacillus of tetanus adds another confirmatory suggestion to the present views of the history of this germ; the pyogenic forms demanding oxygen for their growth, and consuming the limited amount present, thus favoring the conditions for the best development of Nicoläier's germ and offering a convenient soil for its growth.

Granting the probability of a specific nature to the microörganism mentioned, and in view of its localized growth, and its production of tetanogenous alkaloids, what is the mechanism of its action in the production of tetanus? As the sites for its best development, large, open, suppurating or hæmorrhagic sores could not be regarded as affording the proper conditions; but small, quickly-scabbing wounds, or deep, slightly-suppurating punctures, or abscesses almost healed, offer the exclusion of air and the further requisites for its fullest activities. During the period intervening between the time of inoculation and the manifestation of the characteristic phenomena, there probably occurs a gradual increase in the numbers of the microörganisms, and there is elaborated a slowly increasing amount of the special alkaloids described. At first, through the eliminative action of the skin and kidneys, these toxic principles are expelled from the body as rapidly as formed; but with their constant increase, favored perhaps by a temporary failure of these organs of elimination, they finally accumulate sufficiently to render their influences manifest, particularly upon the nervous system. Confirmatory of such a view are the successful attempts in the treatment of tetanus by certain French physicians by the administration of sudorific doses of pilocarpine. The usual treatment of the spasms of tetanus, too, are clearly based upon the idea of the presence in the organism of substances exciting reflex motor spasms, chloral tending to diminish the recognition of afferent impulses and the bromides to decrease the force of the motor explosion following.

PAROXYSMAL HÆMOGLOBINURIA.

One of the most interesting conditions with which clinical medicine has to deal and to which it has paid particular attention during the last few years,

is paroxysmal hæmoglobinuria, either when dependent upon malarial poison or when due to other causes not so clearly defined; and though the studies of Saundby, Murri, Barlow, and others have all tended to throw light upon this question a number of interesting experiments recently published by Dr. S. Monckton Copeman, in the London *Practitioner* for September, 1890, seem to afford conclusive evidence as to some of the causes of its occurrence.

In these studies Copeman found, by a series of careful researches, that exposure to cold in persons susceptible to this condition readily produced hæmoglobinuria, and in this he is interestingly in accord with Johnson, Mahomed, and Ralfe, who have all shown that cold will produce temporary albuminuria.

As the result of his studies Copeman concludes that the essential pathology of paroxysmal hæmoglobinuria appears to consist in the ready breaking-down of corpuscles of lessened resistance under the influence of cold, and the after-appearance in the urine of the products of such destruction; this ready breaking-down of corpuscles being apparently the final result of an imperfect power of production in the blood-forming organs, caused in turn by the baneful influence of syphilis, or possibly malaria or gout.

The details of Copeman's work are very interesting, and anyone interested in this rather uncommon ailment should certainly read his paper.

REVIEWS.

A Manual of Modern Surgery for the Use of Students and Practitioners. By John B. Roberts, A.M., M.D. Illustrated. Philadelphia: Lea Brothers & Co., 1890.

This book of eight hundred pages may be said to represent in a very thorough manner and in a comparatively small space the status of the surgery of the day without presenting to its readers such advanced thoughts as to engender uncertainty in its assertions; and yet all the opinions expressed are sufficiently progressive to make the purchaser feel that in following the advice given he is doing all that the most carefully-trained surgeon could do for his patient. The illustrations, which are very frequently scattered through the entire volume, are, like the text, up to date and unusually well executed. The chapter upon "Injuries to the Nervous Centres" is, we think, a very good one. We notice with interest that in an article upon tetanus, Dr. Roberts makes the somewhat guarded statement that this disease is occasionally contagious, evidently not believing that every case is capable of influencing other cases near it. At the same time the author very properly states that the weight of professional evidence points to the disease being due to a microörganism.

The chapter upon "Diseases of the Abdomen and Pelvis" is very thorough, and notwithstanding the rapid advances made in this portion of surgery is well up to date.

If intrinsic value is the chief factor in making a book sell rapidly, Dr. Roberts's book cannot fail to be a great success.

A Text-book of Comparative Physiology, for Students and Practitioners of Veterinary Medicine. By Wesley Mills, M.A., M.D., D.V.S. Illustrated. New York: D. Appleton & Co., 1890.

Probably no more enthusiastic searcher in the field of comparative physiology can be found in the English-speaking race than Dr. Mills, who, in addition to his laborious researches upon this subject, has within the year past placed before the profession of medicine and veterinary medicine two volumes which are of very great value, and which show that we have on this side of the Atlantic a rapidly-increasing appreciation of the usefulness of a thorough grounding in studies concerning animal life, by those who intend to devote their lives to medicine.

Dr. Mills has, we think, discovered a popular need in the present book, for it is one which medical students, as well as veterinary students, would do well to purchase, and we hope that it will become as widely used as it deserves to be.

The illustrations are unusually well selected and appropriate, presenting to the eye views which impress upon the mind the statements of the text.

SOCIETY PROCEEDINGS.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

The Vice-President, John B. Roberts, M.D., in the Chair.

Stated Meeting, September 24, 1890.

Dr. Joseph P. Tunis read a paper on

RIB-FRACTURE FROM MUSCULAR ACTION,

in which he reported two recent cases and gave a complete review of the literature of the subject. Although some surgeons have denied the possibility of fracture of a rib from muscular action, most admit that it does occur. Of the one hundred and thirty-three cases collected by Gurlt, the majority had some condition present which rendered the ribs easily broken. Any condition which lowers the normal resistance of the bone-structure, such as osteomalacia, rickets, cancer, syphilis, scrofula, advanced age, or atrophy from continuous confinement, etc., must predispose to fracture. "In short, all diseases dependent upon cachexia more or less predispose to the occurrence of fracture," says Hamilton. When some such cause is present the existence of a fracture from muscular action can be readily accounted for. There are, however, numerous cases on record in which such

accidents have occurred in healthy individuals, the determining cause of fracture being muscular action, and the mechanism varying with the anatomy of the affected bone. If these conditions are true for other bones, why may they not be equally true for the ribs?

The ribs offer three factors favorable to fracture: First, their shape; second, their position—firmly attached at the vertebral, and more or less free to move at the sternal end; and third, the powerful muscles attached to their bodies. They are "elastic arches," it is true, and capable of considerable movement; but their elasticity has its limit, and their movements are dependent upon the muscles attached to them. Of these muscles the diaphragm seems to be the most favorably situated to produce rib-fracture. Centrally attached by its crura and ligaments to the vertebral column, it is connected at its circumference "on either side, to the inner surface of the cartilages and bony portions of the six or seven inferior ribs interdigitating with the transversalis." Take, for example, the ninth rib. If the diaphragm should contract, it would draw the anterior third of this bone toward the vertebral column, the other two-thirds being held more or less firmly *in situ* by the serratus magnus, attached posteriorly, the internal oblique, the transversalis, and the intercostals. This contraction of the diaphragm continuing, if sufficiently powerful, would fracture the bone like a bent bow at the point of least resistance. Has the diaphragm sufficient force to accomplish this? It has sufficient force to free the throat or bronchi from irritating material; almost approximates the sternum and the vertebral column in dyspnœa, and often demonstrates this power in membranous croup. It can forcibly eject the contents of the stomach, or cause great distress, and even death, from obstinate hiccough. Well supplied with blood, exercised day and night, we may with some reason believe that, suddenly exerting all its force on three or four ribs, one or more may fracture. Certain it is that the ribs to which the diaphragm is attached are those most frequently fractured.

Above the sixth rib other muscles enter into the mechanism of fracture. In the case which Dr. C. B. Nancrede has reported, and in Dr. Bird's case, where the second rib yielded under unusual muscular strain, the pectoralis minor seems to have been the most probable determining cause, as this muscle is attached to the third, fourth, and fifth ribs, often the second, and is inserted into the coracoid process of the scapula. If the scapula were firmly held in place by the powerful muscles attached to it, the pectoralis minor would be in a position to act with the advantage of leverage. This muscle, or the serratus magnus, would draw the anterior third of the bone away from the vertebral column, directly opposite to the movement of the lower ribs under the action of the diaphragm. Thus the mechanism of a large number of the cases may be explained.

The first case reported by Dr. Tunis was that of a woman, in whom inherited syphilis was suspected, who fractured a rib by a violent paroxysm of coughing.

The second case was observed by Dr. Edward Martin. The patient while lifting a very heavy stone heard a distinct crack and felt an acute, knife-like pain in the left side. On examination the sixth rib was found broken at its sternal end.

Dr. Tunis then briefly described all the cases that have been reported, and concluded with the following deductions:

1. Forty cases having been reported, we may reasonably expect to hear of others, and perhaps to see them ourselves.

2. Of these accidents, more than one-fourth have occurred in individuals of apparently sound constitutions.

3. The left side is most often affected, and either the middle or anterior third of the rib is the usual position of the fracture. Of forty-nine fractures, only five have occurred above the sixth rib. The great majority have been among the lower six (omitting the twelfth).

4. The exciting causes have been: Coughing, muscular effort, sneezing, and vomiting. The determining cause has been the action of the muscles, unless thirty-four observers have been deceived by the testimony of patients who could gain nothing by such deceptions.

5. Herard reports the youngest example of this accident—a woman, twenty-two years old. Its non-occurrence at a younger age is probably due to the great elasticity of the ribs in youth.

6. Of these forty cases, two died of some intercurrent affection. The remaining thirty-eight made a complete recovery in the usual time.

7. More men have suffered than women, and the average age has been forty-eight years.

Dr. Tunis considers that the difficulty and the doubts which have attended the diagnosis of many of these cases ought to disappear, as more examples of this accident are reported. Already, by the consent of the majority of surgeons, and by the evidence of accumulated cases, the possibility of rib-fracture from muscular action, even in persons of sound constitution, seems sufficiently proven.

Dr. Joseph Price then read a paper entitled

CERTAIN CAUSES OF MAJOR PELVIC TROUBLES, TRACEABLE TO MINOR GYNECOLOGY.

Dr. Price said that the popular cry for "conservatism" and preliminary treatment of cases requiring operation is not a scientific plea, but in most instances a *personal bid* for indulgence by those who try to accomplish something, without acknowledging on the one hand that there is little or nothing to encourage them in their work, so far as results are concerned; and on the other, that there is abundant proof that manifold and really major surgical affections arise merely from treatment recognized as orthodox from the standpoint of minor gynecology. Dr. Price said that he did not hesitate to put minor gynecology in a causal relation with a vast amount of the necessary major pelvic surgery.

First among these causes may be mentioned the Emmet cervical operation. Like many other surgical operations, this, when first described by its distinguished originator, was done by every surgeon, without the least consideration of its contra-indications. Very many minor tears of the cervix, in which only a cosmetic effect is obtained by operation, are made distinctly worse by operative interference. In many cases the pain becomes insufferable, from the lighting up of a dormant or unrecognized pelvic trouble, and an operation is required to undo the mischief of an unnecessary cervical closure. This fact has been recognized by Emmet himself, and he has counselled the careful selec-

tion of cases in order to escape these disastrous results. Where there is preëxisting pelvic disease, even though slight, no cervical operation should be attempted unless absolutely required by the condition of the patient.

Another operation which has met with much approval from some men, and which is apparently sometimes successful, is the forcible dilatation of the cervix. It is clear that where there is antecedent inflammation of the pelvic viscera, that is of the genito-urinary system, such an operation as surgical dilatation of the cervix cannot be free from danger. In order to relieve dysmenorrhœa by this procedure, the condition must evidently be due to stenosis of the os or cervix. The question here arises, Can the cause of dysmenorrhœa be determined? Dr. Price thinks that in some cases it can, but that in many women in whom a stenosis would be expected, there is no difficulty whatever attending the menstrual flux. This being the case it is evident that a diagnosis cannot be made without a careful study of all the symptoms.

Again, in many women the causes of this condition are complex. It will not do to lose sight of this, and conclude that because a flexion exists dilatation will remedy menstrual pain. It is to be remembered that if there is coëxisting pelvic inflammation dilatation will increase it, and, under certain conditions, cause it if absent. Rapid dilatation of the cervix is a traumatism, and is attended with all the dangers of septic absorption as is any other violent procedure, and where traumatism incident to natural causes is confessed to be the cause of so much subsequent mischief, it should not be *expected that operative injury can be harmless.*

This conclusion, reached inferentially, Dr. Price said, has been abundantly confirmed practically on the operating-table by much of his later pelvic work. In a number of cases with a history of preceding dilatation, the after-operation shows an exceedingly complicated and inflammatory condition. Some of the dilatations were done during preëxisting disease, which was made worse by the interference, while others were done on uncomplicated cases to relieve the dysmenorrhœa, and resulted in the establishment of a disease in which operation was necessary to save life.

Judged simply by its remoter effects, the operation of rapid dilatation is a dangerous one, and results oftener in subsequent harm than in lasting good. The surgical injury to the cervix is, in many of these cases, more pronounced than the tears of the cervix which are closed by Emmet's operation.

Simple closure of lacerations of the cervix in cases of pelvic disorder, almost certainly exacerbate the symptoms. The necessary inflammatory action set up in the suture-tract is transferred along the lymphatic or venous channels to the seat of the earlier inflammation, until a pelvic peritonitis is kindled or rekindled, which at last entails abdominal section. The minor gynecologist, who has no regard for or appreciation of the relation of the commonly advocated general closure of perineal and cervical tears to major surgical complications, cannot but be a great factor in the causation of the same.

That the inconsiderate use of the uterine sound has been responsible for much inflammatory pelvic trouble is scarcely to be disputed. This is not because the sound is of itself a dangerous instrument, but because it is used by every tyro as an instrument of diagnosis. It used at all, it should be in the hands of those with whom its application, by reason of their skill, will be exceptional, and in the hands of the non-expert its use should be forbidden. The indiscriminate use of the sound and electrode is the most serious mechanical objection to the employment of electricity. Every sitting for the electrical treatment is prefaced by the use of the sound, and necessarily followed by the introduction of an electrode of some form. This is by a class of men who, usually, have had no previous gynecological training or education whatever. In such hands such methods can only be harmful, and we are now reaping the fruits of their work in a class of pelvic operations not surpassed in the complications presented. In the same category with the sound may be placed the curette. Dilatation, with curetting of the uterus, have been the cause of a long series of major operations.

Another class of cases coming under this head are those in which many intra-uterine applications have been made with such agents as nitric acid, chromic acid, and nitrate of silver. For a woman to have undergone a routine treatment with these caustics, and to have escaped pelvic inflammatory trouble, is little short of a miracle.

Dr. E. E. Montgomery, in discussion, fully agreed with what Dr. Price had said with regard to the frequency of troubles necessitating major operations which result from the various methods of procedure in minor gynecology.

The practice of performing Emmet's operation at once upon cases in which a slight laceration is found has justly led to its discredit, although the operation is undoubtedly of great benefit in properly-selected cases. No case in which the presence of inflammatory conditions has not been eliminated or cured by proper methods is suitable for the operation.

Dr. John C. Da Costa thought that Dr. Price was not quite right in attributing the major pelvic troubles to gynecological treatment, for, in most cases, we may infer that the pelvic trouble already existed, and the practitioner made a mistake in treating the uterus rather than the uterine appendages. In regard to Emmet's operation, Dr. Da Costa said that it was often carelessly done on improper cases and without previously preparing the patient.

The uterine dilator he considers a very valuable instrument, but one that must be used with great care.

Dr. Joseph Hoffman referred to a case in which the uterus was perforated by a curette as an illustration of the dangers of the operation.

Dr. William E. Ashton said that if we have the pelvis perfectly free from disease, and if the uterus is strongly anteflexed and perfectly movable, and upon the introduction of the sound we find that there is a point of intense pain at the internal os, we shall find in a certain proportion of cases that good results are obtained from dilatation.

Dr. J. M. Baldy said that he was recently called to operate on the cervix in two cases in which he had been informed that the lacerations were very bad and that the women were suffering greatly. On examination, the tears proved to be comparatively slight, and needed no interference. There are some cases in which a cervix

operation at first sight appears justifiable. These are cases in which the cervix is torn to the vaginal vault; but even if the cervix be torn on both sides to the vaginal vault, if there is not eversion and erosion, or much scar-tissue, there is no reason for operation.

Dr. C. P. Noble said that he was glad that the matter of the uterine sound had been brought up, because he was convinced, as the result of his experience, that the less the uterine sound is used the better for the patient. In most cases but little information is gained. Recently a case passed through his hands in which pregnancy was suspected. The patient afterward fell into other hands, the sound was passed three inches and the patient was supposed not to be pregnant; but subsequent events showed that she was seven months pregnant.

NEWS ITEMS.

The State Board of Medical Examiners of New Jersey.—The following questions were presented to the candidates who appeared before the first meeting of the State Board of Medical Examiners in Trenton, on October 9 and 10, 1890.

It is proper to state that two hours were allowed for replying to each set of questions, and that a general average of 75 per cent. was required to obtain the license:

Section I. Materia Medica and Therapeutics. (Regular.) Dr. Newell.

1. What is glycerin?
2. Name three antiseptics.
3. Write a prescription for acute diarrhœa in a child ten years old.
4. Name two cardiac stimulants and their doses.
5. Name two cardiac sedatives and their doses.
6. What is an emmenagogue?
7. What is iodine?
8. Name three cathartics.
9. Name three laxatives.
10. Write a prescription containing a salt of bismuth.

Section I. Materia Medica and Therapeutics. (Homœopathic.) Dr. Worthington.

1. Explain the theory of "Similia similibus curantur."
2. Give mental symptoms of pulsatilla.
3. Differentiate the skin symptoms of apis mellifica and rhus tox.
4. Give the antidote to ignatia amara.
5. What are the urinary symptoms of lycopodium?
6. Describe the characteristic cough of spongia tosta.
7. Differentiate the throat symptoms of mercurous iodatus rubrum and crotalus.
8. Give the heart symptoms of glonoinum.
9. What are the laryngeal symptoms of kali bichromicum?
10. Give abdominal symptoms of baptistia tinctora.

Section II. Obstetrics and Gynecology. Dr. Brown.

1. Give signs of pregnancy, stating the period at which each appears.
2. Give treatment of placenta prævia.
3. Give diagnosis between ascites and pregnancy at the seventh month.
4. Give treatment of post-partum hæmorrhage.
5. What is the difference between accidental and unavoidable hæmorrhage?
6. What are the indications for craniotomy?
7. Give causes of delay in labor.
8. Give differential diagnosis between ovarian tumor and retroflexion of the uterus.
9. Give causes, symptoms, and treatment of pruritus vulvæ.
10. Give causes, symptoms, and treatment of dysmenorrhœa.

Section III. Practice of Medicine. Dr. Watson.

1. How would you make a physical examination of the thorax?
2. How often, what and how much, would you feed a four months' old bottle-fed infant, in twenty-four hours?
3. Give the complications of pertussis.
4. Give the complications and sequelæ of scarlatina.
5. Give the complications and sequelæ of typhoid fever.
6. Describe a case of cirrhosis of the liver.
7. Give the differential diagnosis between hæmoptysis and hæmatemesis.
8. Give the differential diagnosis between empyæma and pleurisy with effusion.
9. Describe a case of acute meningitis in the adult.
10. Describe a case of acute Bright's disease in the adult.

Section IV. Surgery and Surgical Anatomy. Dr. Hendry.

1. Describe briefly how you would investigate a surgical case, and by what method you would write a history of such a case.
2. Inflammation: (*a*) definition, (*b*) symptoms, (*c*) local effects, (*d*) constitutional effects, (*e*) What is an acute abscess? (*f*) How is pus formed?
3. State briefly your views with regard to the germ-theory of putrefaction as applied to antiseptic surgery.
4. Supposing that in a case of retention of urine from an enlarged prostate, you could not succeed in passing the catheter by the natural passage, what proceeding would you adopt?
5. State the diagnostic characters of carcinoma of the mamma. What are the circumstances which warrant extirpation?
6. State the diagnostic symptoms of the diseases and injuries of the hip-joint.
7. Describe the operation for tying the external iliac artery.

Section V. Anatomy. Dr. Uebelacker.

1. Describe the knee-joint.
2. What muscles are attached to the humerus?
3. Describe the diaphragm.
4. Describe the cæcum and its valve.
5. Describe the pulmonary artery.
6. Describe the pulmonary vein.
7. Describe the circle of Willis.

8. What are the valves of the heart and their functions?
9. Describe the kidneys.
10. Describe the great sciatic nerve.

Section VI. Physiology. Dr. Atwell.

1. What is the reaction of the gastric juice, and from what element is this reaction maintained?
2. Describe the mechanical action of the stomach in the process of digestion, and state what produces it.
3. What is the difference between a secretion and an excretion? Give types of each.
4. Describe the process of oxygenation of the blood, and where does it take place?
5. How does the pulse of a child at the age of one year compare with that of a man at the age of forty years?
6. Where are the distinct seats of motory and sensory properties in the spinal cord?
7. Describe the innervation of the heart.
8. What do you understand by the term reflex action? Give an example.
9. What are the reaction and specific gravity of normal urine, and what is the average quantity for an adult in twenty-four hours?
10. What fluids emptied into the alimentary tract have assigned to them the power of emulsifying and digesting fats?

Section VII. Chemistry. Dr. Tiesler.

1. Explain the three principal modes of fermentation: alcoholic, acetous, and lactic.
2. How many acids of phosphorus are known?
3. What constitutes a sulphide? A sulphite? A sulphate?
4. What do you understand by an element? A molecule? An atom?
5. What is phenol?
6. Name two oxides of hydrogen.
7. How do alkalies and alkaloids differ? Give an example of each.
8. How is nitric acid prepared?
9. What is the difference between calomel and corrosive sublimate?
10. Explain H_2O, H_2SO_4, CO, CO_2, Fe, As_2S_2.

Section VIII. Histology, Pathology, and Diseases of the Eye and Ear. Dr. Wagoner.

1. Give the composition of the blood.
2. In what does human blood differ from that of the frog?
3. Describe the mucous membrane of the stomach.
4. Give the condition of the mucous membrane of the stomach in chronic inflammation thereof.
5. Give the condition of the lung in the second stage of acute lobar pneumonia.
6. What results from embolism of a cerebral artery?
7. Give the treatment of acute conjunctivitis.
8. What are the operations for cataract?
9. Give the prominent symptoms of acute catarrh of the middle ear.
10. What are the sequelæ of purulent inflammation of the middle ear?

Section IX. Hygiene and Medical Jurisprudence. Dr. Worthington.

1. In the physical examination of water what points are to be noted?
2. Are disinfectants more efficacious in the sick-room when used in solution or fumigation?
3. Which is the most powerful disinfectant?
4. How is air vitiated by respiration?
5. In preparing a gallon of a 1-1000 solution of corrosive sublimate, what quantity of the drug is required?
6. In a case of suspected infanticide, what are the most important tests to determine whether the child was or was not born alive?
7. About how soon after death is complete rigor mortis found?
8. What diseases simulate poisoning by arsenic?
9. Differentiate idiocy and insanity.
10. Give all the causes of sudden death.

The Medical Examining Board of Tennessee.—The medical practice act of Tennessee, resembling that of New York, has gone into effect; and the State Board of Examiners, containing representatives of regular medicine, homœopathy, and the eclectics, has been appointed. The hydropaths were left out, and Dr. J. F. Woodward, of McMinnville, who is one of that school, has vented his indignation in a picturesque circular, taking the appointing powers to task for the omission.

Number of Medical Students in Philadelphia for the Session of 1890--91.—The following list of the number of medical students who have so far matriculated in Philadelphia regular schools up to date is of interest.

Medical Department University of Pennsylvania:

First year	220
Second year	186
Third "	165
Fourth "	4
Total	575

Jefferson Medical College:

First year	212
Second year	175
Third "	135
Total	522

Medico-Chirurgical College, total, 123.

Woman's Medical College has no information to give until November 1st, or until all the students will have registered.

It is generally estimated that about 30 more men will matriculate at the Jefferson, and 20 at the University.

The number of students at the Hahnemann School is 206.

Vaccination in France.—The special committee appointed by the Academy of Medicine, at Paris, to inquire anew into the prophylactic value of vaccination, have made a report strongly in favor of the adoption of laws that will make vaccination and revaccination compulsory in France.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM OCTOBER 7 TO OCTOBER 13, 1890.

By direction of the Secretary of War, ARTHUR W. TAYLOR, *Captain and Assistant Surgeon*, is relieved from duty at Fort Wingate, New Mexico, to take effect on the expiration of present sick-leave, and will report in person to the commanding officer Fort Adams, R. I., for duty at that station, relieving J. J. Cochran, Captain and Assistant Surgeon. Captain Cochran, upon being relieved by Captain Taylor, will report in person to the commanding officer Camp Eagle Pass, Texas, for duty at that station, relieving Paul Clendenin, First Lieutenant and Assistant Surgeon. Lieutenant Clendenin, on being relieved by Captain Cochran, will report in person to the commanding officer Fort Brady, Mich., for duty at that station.—Par. 8, *S. O. 232, A. G. O., Washington, D. C.*, October 3, 1890.

By direction of the Secretary of War, WALTER REED, *Captain and Assistant Surgeon*, is relieved from further duty at Mount Vernon Barracks, Ala., and assigned to duty as Attending Surgeon and Examiner of Recruits at Baltimore, Md.—Par. 7, *S. O. 233, A. G. O., Washington, D. C.*, October 4, 1890.

By direction of the Secretary of War, leave of absence for three months is granted ROBERT J. GIBSON, *Captain and Assistant Surgeon*, to take effect on being relieved from duty at Fort Trumbull, Conn., by Henry M. Cronkhite, Major and Surgeon.—Par. 12, *S. O. 232, A. G. O., Washington, D. C.*, October 3, 1890.

By direction of the Secretary of War, C. N. BERKELEY MACAULEY, *Captain and Assistant Surgeon*, is relieved from duty at Fort Supply, Indian Territory, and will report in person to the commanding officer Fort Lewis, Colorado, for duty at that station.—Par. 2, *S. O. 233, A. G. O., Washington, D. C.*, October 4, 1890.

By direction of the Secretary of War, ROBERT B. BENHAM, *Captain and Assistant Surgeon*, will proceed from Fort Hamilton, N. Y., to Mount Vernon Barracks, Ala., and report in person to the commanding officer of that post for temporary duty, relieving John J. Cochran, Captain and Assistant Surgeon, who will return to his proper station.—Par. 8, *S. O. 232, A. G. O., Washington, D. C.*, October 3, 1890.

By direction of the Secretary of War, RUDOLPH G. EBERT, *Captain and Assistant Surgeon*, is relieved from duty at Angel Island, Cal., to take effect upon the arrival at that post of William H. Gardner, Major and Surgeon, and will then proceed to Vancouver Barracks, Wash., and report to the commanding officer of that post for duty.—Par. 15, *S. O. 232, A. G. O., Washington, D. C.*, October 3, 1890.

By direction of the Secretary of War, ALLEN M. SMITH, *First Lieutenant and Assistant Surgeon*, is relieved from duty at Fort Snelling, Minn., and will report in person to the commanding officer Fort Assiniboine, Montana, for duty at that station, relieving Paul Shillock, First Lieutenant and Assistant Surgeon. Lieutenant Shillock, upon being relieved, will report in person to the commanding officer Fort Custer, Montana, for duty at that station, relieving William R. Hall, Captain and Assistant Surgeon. Captain Hall, upon being relieved by Lieutenant Shillock, will report in person to the commanding officer Fort Schuyler, N. Y., for duty at that station, relieving Norton Strong, Captain and Assistant Surgeon. Captain Strong, on being relieved by Captain Hall, will report in person to the commanding officer at Fort Meade, South Dakota, for duty at that station.—Par. 8, *S. O. 232, A. G. O., Washington, D. C.*, October 3, 1890.

By direction of the Secretary of War, VAN BUREN HUBBARD, *Major and Surgeon*, is relieved from duty at Columbus Barracks, Ohio, and will report in person to the commanding officer Fort Spokane, Washington, for duty at that station, relieving Henry S. Turrill, Captain and Assistant Surgeon. Captain Turrill, upon being relieved by Major Hubbard, will report in person to the commanding officer Madison Barracks, N. Y., for duty at that station, relieving John D. Hall, Major and Surgeon. Major Hall, on being relieved by Captain Turrill, will report in person to the commanding officer Fort Canby, Wash., for duty at that station.—Par. 8, *S. O. 232, A. G. O., Washington, D. C.*, October 3, 1890.

By direction of the Secretary of War, the following changes in the stations and duties of officers of the Medical Department are ordered:

STERNBERG, GEORGE M., *Major and Surgeon.*—Is relieved from duty as Attending Surgeon and Examiner of Recruits at Baltimore, Md., and as a member of the Army Medical Board appointed to meet in New York City, N. Y., and will repair to San Francisco, Cal., and take charge of the Medical Purveying Depot at that place, as Acting Assistant Medical Purveyor, relieving B. J. D. Irwin, Colonel and Surgeon. Colonel Irwin, on being thus relieved, will report in person to the commanding general Department of the Columbia, for assignment to duty as Medical Director of that Department, and as Post Surgeon, Vancouver Barracks, Wash., relieving William E. Waters, Major and Surgeon, now Post Surgeon, and temporarily in charge of the Medical Director's Office. Major Waters, on being thus relieved, will report in person to the commanding officer Fort Custer, Mont., for duty at that station.—Par. 8, *S. O. 232, A. G. O.*, October 3, 1890.

By direction of the Secretary of War, CURTIS E. MUNN, *Major and Surgeon*, is relieved from duty at Angel Island, Cal., and will report in person to the commanding officer Fort Monroe, Va., for duty at that station, relieving John Brooke, Major and Surgeon. Major Brooke, on being relieved by Major Munn, will report in person to the commanding officer Fort Leavenworth, Kansas, for duty at that station, relieving Alfred A. Woodhull, Major and Surgeon. Major Woodhull, on being relieved by Major Brooke, will report in person to the commanding officer Fort Sherman, Idaho, for duty at that station.—Par. 8, *S. O. 232, A. G. O., Washington, D. C.*, October 3, 1890.

By direction of the Secretary of War, WILLIAM C. BORDEN, *Captain and Assistant Surgeon*, is relieved from duty at Fort Sam Houston, Texas, upon the arrival of C. C. Byrne, Lieutenant-Colonel and Surgeon, and will report in person to the commanding officer Fort Davis, Texas, for duty at that station, relieving Peter R. Egan, Captain and Assistant Surgeon. Captain Egan, upon being relieved by Captain Borden, will report in person to the commanding officer Fort Warren, Mass., for duty at that station, relieving George McCreery, Captain and Assistant Surgeon. Captain McCreery, on being relieved by Captain Egan, will report in person to the commanding officer Fort Clark, Texas, for duty at that station, relieving Charles M. Gandy, Captain and Assistant Surgeon. Captain Gandy, on being relieved by Captain McCreery, will report in person to the commanding officer Fort Shaw, Montana, for duty at that station.—Par. 8, *S. O. 232, A. G. O., Washington, D. C.*, October 3, 1890.

By direction of the Secretary of War, WILLIAM H. GARDNER, *Major and Surgeon*, is relieved from duty at Washington Barracks, District of Columbia, to take effect upon the arrival of Joseph K. Corson, Major and Surgeon, and will report in person to the commanding officer Angel Island, Cal., for duty at that station.—Par. 8, *S. O. 232, A. G. O., Washington, D. C.*, October 3, 1890.

By direction of the Secretary of War, HENRY M. CRONKHITE, *Major and Surgeon*, is relieved from duty at Fort Lewis, Colorado, and will report in person to the commanding officer Fort Trumbull, Conn., for duty at that station, relieving Robert J. Gibson, Captain and Assistant Surgeon. Captain Gibson, on being relieved from duty by Major Cronkhite, will report in person to the commanding officer Fort Sam Houston, Texas, for duty at that station.—Par. 8, *S. O. 232, A. G. O., Washington, D. C.*, October 3, 1890.

By direction of the Secretary of War, the leave of absence granted LEONARD WOOD, *First Lieutenant and Assistant Surgeon*, in Special Orders No. 74, August 30, 1890, Department of California, is extended one month.—Par. 7, *S. O. 232, A. G. O., Washington, D. C.*, October 3, 1890.

BAILY, JOSEPH C., *Lieutenant-Colonel, Assistant Medical Purveyor, and Medical Director of the Department of Texas.*—Is granted leave of absence for one month.—Par. 3, *S. O. 86, Department of Texas*, October 3, 1890.

By direction of the Secretary of War, JAMES A. FINLEY, *Captain and Assistant Surgeon*, is relieved from duty at Fort Totten, North Dakota, and will report in person to the commanding officer Jefferson Barracks, Mo., for duty at that station, relieving William D. Crosby, Captain and Assistant Surgeon. Captain Crosby, on being relieved by Captain Finley, will report in person to the commanding officer Fort Pembina, North Dakota, for duty at that station.—Par. 8, *S. O. 232, A. G. O., Washington, D. C.*, October 3, 1890.

BYRNE, CHARLES C., *Lieutenant-Colonel and Surgeon.*—Is relieved from duty as Attending Surgeon at the Soldiers' Home, near this city, and will report in person to the commanding officer Fort Sam Houston, Texas, for duty at that station.—Par. 8, *S. O. 232, A. G. O., Washington, D. C.*, October 3, 1890.

APPOINTMENT.

VOLLUM, EDWARD P., *Colonel and Surgeon.*—To be Chief Medical Purveyor, with the rank of Colonel, August 28, 1890.

PROMOTIONS.

IRWIN, BERNARD J. D., *Lieutenant-Colonel and Assistant Medical Purveyor.*—To be Surgeon, with the rank of Colonel, August 28, 1890.

FRYER, BLENCOWE E., *Major and Surgeon.*—To be Assistant Medical Purveyor, with the rank of Lieutenant-Colonel, August 28, 1890.

COWDREY, STEVENS G., *Captain and Assistant Surgeon.*—To be Surgeon, with the rank of Major, August 28, 1890.

ORIGINAL LECTURES.

PHANTOM TUMORS—ABDOMINAL DROPSY—OVARITIS—FIBROID TUMOR OF THE UTERUS.

A Clinical Lecture
delivered at the Hospital of the University of Pennsylvania, September 24, 1890.

BY WILLIAM GOODELL, M.D.,
PROFESSOR OF GYNECOLOGY.

Reported by LEWIS H. ADLER, JR., M.D.,
RESIDENT PHYSICIAN OF THE EPISCOPAL HOSPITAL; LATE RESIDENT PHYSICIAN OF THE UNIVERSITY HOSPITAL.

GENTLEMEN: The first case that I present to you is one of a kind that often puzzles physicians. The patient is past the age of forty-nine years; her youngest child is over twelve years of age. An enlargement of the abdomen has been present for seven years, and she has intermenstrual pains. In order to ascertain her condition, I shall examine her first without an anæsthetic and, finally, under ether.

Phantom tumors occurring in this region, on superficial examination resemble genuine tumors and are very deceptive, but usually they will be found to be resonant on percussion.

In this case there is a prominent and resonant abdominal tumefaction, but I find that I can come to no positive conclusion until the woman is etherized. If there be a tumor, the intestines clearly lie above it. When she came to my office, a short time ago, there was even more distention than now, owing, perhaps, to greater flaccidity of the abdominal walls, and, consequently, to their greater distention by the bloated intestines.

Before proceeding further with the case, I shall have the patient removed from the clinic-room and anæsthetized, in order to be more certain in rendering my decision. If there be no fluctuation, there is no liquid; and if in front of the tumor there is a resonant mass, due to the accumulation of fat and gas, the only way for us to dispel this doubt, or, at least, to lessen greatly the difficulty of the diagnosis, is to use ether, for, the presence of the gas being mostly a nervous phenomenon, it is largely dispelled by this means.

Phantom tumors most frequently occur in women at the time of the menopause. Many physicians make the mistake of imagining women with such an enlargement to be pregnant, and are surprised and mortified to discover their error. A case will occur somewhat in this manner: A woman approaches the age of forty-five years; she loses her periods; fattens, and her abdomen becomes distended with gas. She at once concludes that she is pregnant, and announces the fact to her husband and intimate friends. Those in the secret patiently await the advent of labor and hold themselves in readiness to congratulate her upon the Benjamin of her old age. The family physician defers his summer vacation, and everything, even down to a handy pincushion, is ready for the little stranger. But, lo! when the expected time arrives all are wofully disappointed. Days and weeks pass by, but still no child is born. The whole affair was due to fat and gas. If the woman had been examined under ether, such a failure in diagnosis would not have been made. Nor is this mistake of imagining themselves pregnant, when they are not, confined alone to human females. A bitch will make all preparations for her expected litter, and be disappointed for exactly similar reasons.

Phantom tumors are provoking, as well as deceptive, to physicians. A woman goes from one to another, and is not benefited. The reason is because she is not anæsthetized and examined *per vaginam* by the double touch. Sir James Y. Simpson, the distinguished gynecologist, now dead, meeting in his practice one of these patients who had thus, without etherization, been going from one doctor to another, put her under the influence of an anæsthetic, and that, too, in the presence of her sister, who was also allowed to examine her abdomen. As the patient recovered consciousness, she still contended that she was pregnant, when her sister contradicted her by saying: "Hush, Hettie, hush! ye ha' nae chiel in your wame, for I felt your back-bane."

In the patient before you, as her bowels move freely, the abdominal swelling cannot be due to any obstruction in the intestines, because where faeces can pass, gas can pass. As I previously stated, this distention is often due to nervousness. I had a patient who used to come to my office for examination, upon whose abdomen I could have beaten a "reveille." When she was etherized, the distention wholly disappeared.

In the present case Dr. Taylor is doing the percussing for me, as my fingers are engaged in holding the abdominal wall. I grasp the abdominal walls firmly in my hand, and when the woman becomes thoroughly etherized, and consequently entirely relaxed, I shall be able to obtain even a better hold. While I am so engaged, Dr. Taylor elicits no fluctuation in the portion of the abdomen remaining below and finds no evidence of a tumor.

I also thought that an abdominal hernia might be the cause of all this woman's trouble. There is sometimes a natural separation of the recti muscles, allowing a protrusion of the intestines, which constitutes what is known as ventral hernia; and, moreover, this affection sometimes follows ovariotomy.

The rule by which you are to guard against mistakes is to insist upon the use of the *double touch*, as well as the examination *per vaginam*. By these means I am enabled in many cases to outline accurately the size of the included uterus.

In the present case, by passing two fingers of the left hand into the vagina and then meeting them with the fingers of the right hand placed on the outside of the abdomen, I find that the left ovary is doubtlessly enlarged; the other ovary may also be in the same condition. But this condition will not account for the largeness of the abdomen, which is to be explained not alone by omental fat, and by the thickness of the abdominal walls, but also by their flaccidity and distention by large quantities of gas.

The treatment upon which I should like to put this woman is that of asafœtida in large doses—not one or two grains, but nine grains, three times a day, before meals, in three-grain *sugar-coated* pills, so that she will not taste them after they are swallowed. After three days, this trouble of tasting the medicine generally ceases, and she would then be able to take twelve grains three times a day if needful.

Now, in this case there are some, but not sufficient, indications to perform abdominal section. In former times the exploratory incision was done even more than it is nowadays, in order to arrive at a positive diagnosis; but this is not necessary at present, owing to the introduction of anæsthetization as a preliminary step to a thorough examination. Therefore, you will have learned another golden rule by which you may be guided in your practice, and that is: if a woman with an enlarged, resonant, but not fluctuating, abdomen comes to you, act upon the supposition that there is no tumor present, but only gas. If you then err it will be on the safe side.

ABDOMINAL DROPSY.

Physicians sometimes mistake pregnancy for tumors, because they are liable to meet with cases of pregnancy when they are not expecting them, and when they ought, morally, not to occur, even among the higher classes. In such cases always inquire about the menstruation, and if it has ceased, always think first of pregnancy as being the cause of its stoppage. If the case be one of dropsy, it has its cause somewhere in the great tripod of life—the heart, the liver, or the kidneys—and means a constitutional trouble with constitutional disturbances. We get in such cases, resonance. Why? Because the intestines are floated upon the fluid, unless they be bound down by old inflammatory adhesions, or unless the belly is so distended that a wide space exists between the intestines and the abdominal wall, which space is filled with fluid.

OVARITIS.

The next patient is twenty-three years old. She has been married for three years and has an abdominal growth. She complains of a pain in the left side of the abdomen, running down the inside of the thigh, along the course of the genito-crural nerve. Such pain is sometimes due to ordinary sciatica, but it is not so in her case. Her menstruation is painful and profuse, which may mean something or nothing.

I now begin our examination, in which I use my finger, not the speculum, which, as a rule, should be reserved for treatment only, for upon one's finger one can acquire a degree of sensitiveness, of education, which must always remain strangers to any instrument. Upon making this examination, I find what is called a *sickle-shaped* cervix. The womb is pushed over to the left by a tumor on the right side, which is round, not in the form of a sausage, like that of a prolapsed and enlarged tube. Therefore, it is an ovary, and, if it arises from a constitutional cause, a cold, a peritonitis, or any of the exanthemata, as it does in this case, the other ovary is most apt to be affected, and both will have to be removed. This, while it is a painful operation, is not a very dangerous one.

Such constitutional manifestations of cold often follow exposure, especially such indiscretion as sitting upon cold steps at night during menstruation.

After marriage the great cause of ovaritis is the contraction of gonorrhœa from the husband. Then there may be much inflammation, an abundant exudation of plastic lymph, and the organ becomes bound down by adhesions to adjacent structures, causing upon each movement of the woman sickening pain similar to that sometimes experienced in the analogous organ in the male. The other ovary, not primarily the seat of any germs, may be all right.

FIBROID TUMOR OF THE UTERUS.

Double touch proves the gynecologist. I know of a doctor, well posted on general medicine, who, when a woman came to him for treatment for some obscure pelvic trouble, after an imperfect examination, simply inserted a pessary into the vagina. It is needless to say that, even as a palliative measure, it was a failure. A rule, then, for you to remember henceforth is that if a physician does not know how to examine a woman by the *double touch*, he knows nothing about gynecology. A recent graduate, whether from this or any other first-class college, can do more in a case like the patient I now bring before you than many of the older physicians who did not have an opportunity to learn these methods of diagnosis at college, and who since have not thoroughly kept up with the subject.

This woman is forty years of age, and has been married for many years. Seven years ago she miscarried and gave birth to a dead fœtus. For five years subsequent to this abortion she had no menstrual flow. Whenever you meet an abortion, no matter where, the question that should first come into your minds is: Can this be due to syphilis? Examine both the man and woman, if possible, asking not only whether they ever had syphilis—for they may not know what that means—but whether they have ever had a sore on their privates, or the mucous patches, eruptions, and other manifestations of the disease, upon the other parts of their bodies. In this case, the first thing that strikes us in our examination is that the nymphæ are very much enlarged. If she were unmarried, I should think first of self-abuse, though I should not be certain that this was the cause. You can see that these nymphæ are flattened and elongated. In the Hottentot women they extend nearly to their knees, and, are considered ornamental.

I now pass in the uterine sound, and, in doing so, resort to the "master's wrinkle." This consists in introducing the instrument into the cavity of the uterus by pressing the handle down, raising it, and then depressing it, when in it goes. We have here a large fibroid of the uterus. I think there is also a smaller fibroma to the right of the uterus—a sub-peritoneal fibroid.

What is to be done in such cases? Now, as this is a tumor that rarely kills, the question is whether the woman is suffering sufficient pain or annoyance for me to operate. The uterus might be removed; but this is hardly ever needful in such cases. The operation generally resorted to is oöphorectomy, because by this means the monthly flow of blood to the organ is stopped, and the tumor ceases to grow, from lack of nutrition. If, however, you refuse to operate, or the patient be afraid to run the risks incident thereto, you can put her on the two medicines, ammonium chloride and fluid extract of ergot —say, ten grains of the former, which is the great absorbent, and from fifteen to twenty drops of the latter, which, by cutting off the blood-supply from the tumor, cause it to cease to thrive and will gradually make it lessen in size. These medicines are to be taken three times a day, and preferably at meal-times, lest from the action of ergot on the vasomotor nerves, nausea and digestive disturbance be occasioned. Again, fibroid tumors being flesh tumors, not cystic, they increase slowly in comparison with fluid tumors until the change of life, when they either cease to increase or lessen in size. If the change of life is deferred until later, these tumors may become fibro-cystic, and sometimes cancerous; but, as I have never met with an instance of the latter in my practice, when women become nervous and question me on the subject, I hoot at the idea. If, on the other hand, a woman with a fibroid tumor be not well-off pecuniarily, so as to live a life of ease, nor free from pain, I generally advise the removal of her ovaries. In this case I shall put the woman upon the above-mentioned medicines until I can more thoroughly study her case.

These three cases, then, are of great interest, because they are intensely practical. The first teaches the lesson that phantom tumors are to be studied most carefully, and that, too, with the woman under ether, as well as that the great medicine for phantom tumors is asafœtida.

The second case is one of ovaritis, following scarlet fever, in which, as both organs are nearly always affected, the treatment consists in double ovariotomy.

The third case is that of a uterine fibroid, which can be treated either by laparotomy or by the medicines, ammonium chloride and ergot, always remembering that, if the woman can be tided over the years of her menstruation, the tumor will then cease to give trouble and decrease in size, even if it does not entirely disappear.

ORIGINAL ARTICLES.

SOME OF THE DIFFICULTIES MET WITH IN ABDOMINAL SURGERY, AS ILLUSTRATED BY CASES FROM PERSONAL RECORDS.[1]

By A. VANDER VEER, M.D.,

PROFESSOR OF DIDACTIC, ABDOMINAL, AND CLINICAL SURGERY IN THE ALBANY MEDICAL COLLEGE, ALBANY, N. Y.

I have thought it well to present these cases that to myself have suggested many anxious thoughts and some misgivings. It has seemed to me wiser to do this than to offer a series of cases covering a number of months since my last records were given to the profession. It would be far more pleasing to offer a full report of all cases operated on, but such a report would necessarily contain a number of simple cases, without interest in diagnosis or treatment. It is also true that in presenting these cases as I do, the cynic and the iconoclast may visit upon me an undue amount of criticism. This is something, however, that can be taken care of in the future. What I desire, is to bring out the strong fact that the reading and thinking public, the intelligent classes, have been led to believe that the surgeon can successfully do almost any operation within the pelvis and abdomen.

Is this true?

As one doing considerable abdominal surgery in a large section of the country, I must, looking at the subject from one standpoint, answer the question in the negative. Looking at it from another standpoint, I can most earnestly answer it in the affirmative. The factors that will ever enter into the latter answer are the early recognition of abdominal disease by the family physician, and also the desire to call the surgeon early, if only to make a diagnosis.

The negative answer is one with which the public is greatly concerned. What can we promise to the friends of the patient whose case, either from traumatism or acute or chronic conditions, becomes one for abdominal surgery? We know that the accumulated experience of the past few years has thrown upon this subject an immense flood of light; but more is needed. This paper is offered with the hope that as the subject emerges from discussion it may be clearer to us all.

Case 1.—Miss S. M., aged twenty-four years, a domestic. Admitted to the Albany Hospital, September 17, 1888. She gave the history of a tumor first noticed eighteen months previously, and which was diagnosed soon after as being entirely within the pelvis. Her menstruation had been fairly regular, but during the past six months the tumor had grown quite rapidly, giving her more pain, and she was losing flesh so rapidly as to alarm her friends. Up to this time she had opposed an operation.

On careful examination the tumor was found to fill the pelvis and to extend to the umbilicus, and was somewhat sensitive and movable as the patient was turned from side to side. No ascites. Tumor was hard and elastic. Cervix well defined, but the body of the uterus could not be outlined.

Diagnosis: Probable fibro-sarcoma of the broad ligament. Exploration by abdominal section was advised with a view to remove the growth if possible.

Operation, September 27, 1888: The tumor was found to occupy about the position described above, and was entirely connected with the left broad ligament, with many deep adhesions within the pelvis and about the sigmoid flexure.

No abdominal adhesions of importance. A num-

[1] Read before the American Association of Obstetricians and Gynecologists, Philadelphia, September 17, 1890.

ber of ligatures were applied to the points of adhesion, and the pedicle, made from the broad ligament and the adhesions, was secured by a Staffordshire knot. The pelvis was cleansed by sponging and no serious oozing appearing; the abdomen was closed without drainage in the usual manner.

The patient rallied from the operation and did well until the beginning of the third day, when nausea began, followed in twelve hours by vomiting. Rectal injections, small doses of calomel, and one-drachm doses of sulphate of magnesium failed to produce any movement of the bowels, and but little gas passed. Patient did not suffer very severe pain, but there was considerable distention of the abdomen from intestinal gas. The vomited material at first was spinach-like; a few hours before her death it became more fæcal in character. The patient died about 4 P.M., October 2d, death beginning with cold hands and feet.

I thought that she died from traumatic peritonitis, but the autopsy showed that a coil of the ileum had become attached to the sigmoid flexure, where the adhesions had been separated, and had doubled upon itself, causing obstruction of the bowels, which was the true cause of death.

This was in October, 1888. Who will deny that, had I opened the abdomen on the third day, found the point of obstruction, loosened the adhesions, and flushed the abdominal cavity with hot water, the patient would have recovered? Again, in all such cases, especially where we have reason to believe that the growth is a sarcoma, or a true carcinoma, with adhesions, is it not better to flush the cavity and to leave it filled with the fluid, not using a drainage-tube, in order that the intestines may continue to float for some time after the operation?

Case II.—Mrs. H. M., aged thirty-one years, married, the mother of three living and healthy children, of which the oldest is aged six years. Family history good. Father died at the age of fifty-three years of paralysis, though he occasionally suffered from stomach trouble. Mother living at the age of sixty. Three brothers and four sisters living.

The patient began to menstruate at the age of fourteen years, and was regular up to seven months ago, when the flow ceased. When nineteen years old she had an attack of what was termed dyspepsia, and was very ill for two months. Since then she has had similar attacks about once a year, lasting from two to three months. They are always accompanied with more or less pain throughout the abdomen. Her last child was born in July, 1887, and since then she has had more or less nausea, with vomiting, and has gradually lost flesh.

About the latter part of July, 1888, she noticed an enlargement in the abdomen a little to the right of and above the umbilicus. Her family physician had called three or four consultants, and the consensus of opinion was that she had carcinoma of the pylorus.

She was admitted to the Albany Hospital, November 20, 1888. She was much emaciated. There was little intestinal distention, except about the ileo-cæcal region. Above this point could be felt a hard mass, nearly circular in outline, and about the size of two fingers. She had been much constipated at times, but whenever her bowels could be moved and kept moving she felt much better. When she vomited it was first the food or drink that she had recently taken, then a dark, greenish-looking fluid, at times becoming fæcal in appearance and odor. Stomach not distended.

I believed that she had a malignant growth implicating some portion of the intestine near the ileo-cæcal region.

An exploratory section was advised with the understanding that if possible the growth should be removed. I was also prepared to do an intestinal anastomosis if that became necessary.

Operation, November 23, 1888: A section through the right linea semilunaris was made, the patient having been previously prepared. There was found a projecting tumor near the junction of the ascending and transverse colon, from which adhesions extended around the gut, entirely closing its calibre. The tumor seemed to pull down and hold the intestines quite firmly in the lumbar regions. I loosened these adhesions and, believing the tumor to be malignant, concluded that it was best to make the operation as short as possible; hence after exploring the pyloric end of the stomach I closed the wound. Though very weak she bore the operation well and returned to a fairly good condition within twelve hours.

The wound closed perfectly, and the patient had a number of good fæcal movements in the few days following the operation. She vomited occasionally, and at times there would be traces of blood with the mucus from the stomach, but no substance resembling fæcal fluid was ever observed. After the tenth day she was able to take more food than at any time for a year previously. At times she complained of distress about the stomach, saying that it was distended with gas, and that she still felt the old indigestion. At times she would feel much better, and she gained sufficiently to walk about her room. At other times for a day or two she would frequently vomit a dirty, brownish-looking fluid. She could not take solid food with comfort. Bowels would move each day with the aid of a mild enema. During her convalescence she occasionally took anodynes, but not to any extent. Cocaine often relieved the gastric distress, as did various other remedies.

She returned to her home, December 19th, much improved in her general health. To her husband, herself and friends I stated that she had a malignant growth which it would not be safe to undertake the removal of, and that the occasional unpleasant symptoms were probably due to secondary deposits in the walls of the stomach. At her home, as her family physician, Dr. Popen, informed me, she remained very comfortable for weeks. At times the tumor was more distinct than at others. At one time, for a few days, she seemed so well that her husband came to my office and asked me frankly if

it were not possible that a mistake had been made in the diagnosis. But gradually the vomiting of mucus, and especially recently-taken fluids, became more serious, and she finally died of exhaustion.

Autopsy, made by Drs. Popen, Marselius, and Macdonald, revealed an hour-glass contraction of the stomach near the cardiac end; bands of adhesions closing the stomach so completely that only a probe could be passed through the stricture. These adhesions were very firm. The entire intestinal tract was normal. The supposed malignant tumor proved to be a displaced kidney, firmly adherent in its new position, but normal. I think it not improbable that at one time this was a floating kidney, that at times it produced sympathetic disturbance of the stomach, that she had many attacks of acute gastritis, occasionally accompanied with local peritonitis, and that in one of these latter attacks the kidney became fastened by the new adhesions.

Should I have discovered the hour-glass contraction of the stomach at the time that I made the section? If I had, is there much probability that I could have loosened the adhesions? The latter I believe could have been done by making an anastomosis of the lower end of the duodenum or upper portion of the jejunum with the cardiac end of the stomach. But would we have been justified in doing this in the face of our supposed malignant tumor?

Case III.—Mrs. L. R., married, no children, family history of tuberculosis. She has some cough, and marked dulness over the apex of the left lung.

Admitted to the Albany Hospital, November 10, 1888. One year ago she noticed an enlargement on the right side of the abdomen, which has gradually increased, and she now presents a well-marked ovarian cyst. Operation was advised to relieve the patient of her anxiety, in the belief that she had sufficient strength to recover.

Operation, November 12, 1888: The pedicle was very short and was ligated with soft Chinese silk, which I had previously used in similar operations, but in this instance the wax had been removed, which made the silk very soft, pliable, and easily handled. This patient did well until the end of the third day when she began to show symptoms of septic peritonitis and died soon afterward.

Autopsy: The ligature was found completely softened, loosened, and very friable. There had been some hæmorrhage, but not extensive, from the pedicle and the whole peritoneal cavity was filled with pockets of pus.

It is possible that the general constitutional condition of this patient may have had something to do with the causation of the peritoneal complication, but undoubtedly the imperfect ligature acted as the exciting cause.

There is no doubt that the patient would have been benefited by reopening the abdomen on the fourth day, washing it out, putting in a drainage-tube, and, if necessary, controlling hæmorrhage. The case has been a warning to me not to make use of this kind of ligature.

Case IV.—Mrs. G. T., aged fifty-one years, has had one child and several miscarriages. Her family history is good. She first noticed an enlargement of the abdomen some five years ago, but it has become more marked during the past two years, and especially during the past year and a half. She has lost much flesh.

The patient has passed through much family affliction, losing her only child at the age of twenty years, and her parents soon after. Her menstruation has usually been regular, but at times very excessive. During the past year the flow has not been so great and has occurred every two or three months only.

In the past three years she has had a number of attacks of local peritonitis accompanied with much pain, and has been obliged to take morphine freely, having taken for a long time previously to the operation, eighteen grains in the twenty-four hours. Her physician had made the diagnosis of ovarian tumor, and this I had only to confirm, though believing that it was possibly complicated with a fibroid of the uterus.

The case was plainly a multilocular tumor, and could be easily defined when I first saw the patient with Dr. L., and while agreeing with him as to the necessity of an operation, yet I was anxious to postpone it if possible until the weather became somewhat cooler. However, she was losing ground, and while she had previously opposed an operation, it was now evident to her that her only hope was in an operation. She was anxious to be tapped, but this we positively declined to do, assuring her that it could do little good, there being evidences of many cysts. Her face presented the appearance so characteristic of ovarian disease.

Her condition grew so serious that we concluded to do the operation. We prepared a room in her own house, and secured two of my best trained nurses. The patient's friends were opposed to the operation, and some of my acquaintances thought I was foolish to operate in so serious a case.

Operation, August 28, 1889: The tumor was composed of more cysts than I had ever seen, and their contents, in color, consistence, etc., were as varied as possible. There were adhesions to every organ within the abdominal cavity. These were loosened by a sponge and the fingers, and much time was consumed in applying ligatures. A long and tedious operation resulted in the removal of a tumor weighing fifty-six pounds. (The patient's average weight in early life was ninety pounds.) The abdomen was thoroughly flushed with hot water, which was allowed to remain. A glass drainage-tube was placed in the lower end of the incision. For three days the hæmorrhage was considerable, and at times so serious as to give me much anxiety. I then suggested to Dr. Macdonald, my assistant, who had remained with the patient at night, to inject a solution of the subsulphate of iron through the tube. Hæmorrhage then ceased, oozing grew less and less,

and the tube was removed on the ninth day. The patient for forty-eight hours required large doses of morphine, after that less, and in time she reached a very small dose, and I think that the habit is now broken. She made a good recovery, and to-day herself and friends are more than grateful.

What anxiety would have been spared me, as the operator, had she submitted to an early operation.

Case V.—On the evening of October 14, 1889. I received a telegram requesting me to come about twenty miles in the country to see a case of intestinal obstruction, and, if necessary, to operate. I was tired and the last evening train had left, but my assistant, Dr. W. G. Macdonald, responded to the call, and found the patient a laborer, aged forty-two years, with such surroundings that it seemed impossible to do any operation there. Accordingly, he was brought to the Albany Hospital early on the morning of October 15th.

Patient was well developed, and weighed about 160 pounds. Previous health good. At the age of seventeen years he developed a left inguinal hernia, which had not given him much trouble until three years ago, when his usual truss failed to retain it. He then grew careless, often going without any truss. On October 5, 1889, the bowel escaped quite freely, but he lay down in his usual position, and thought that he replaced it. After a hearty dinner of beans, etc., he was taken with vomiting, and had to give up work. Vomiting continued for two days. He did not have severe pain until the third day. No movement of the bowels could be obtained either by injections or medicines. On October 9th, there was no appearance of a hernia, but much soreness on the left side. The fourth day pain and vomiting ceased, and the abdomen became greatly distended.

When I saw him on the morning of October 15th he presented an anxious appearance, sunken eyes, cold extremities, cyanosis, subnormal temperature, husky voice, restlessness, and every symptom of approaching death. His pulse was 140 to 150.

It is in this condition that we are too often called to see cases of abdominal surgery.

My first impulse was to make an incision directly over the seat of his old hernia, and look for the trouble there, but I finally concluded that about the only thing I would be able to do would be enterostomy.

Operation: I made the median section, giving very little ether, and passed in two fingers on either side, but did not detect any trouble at either of the rings. I then brought out at the opening what I believed to be a fold of ileum, incised it, emptied out a great quantity of gas and liquid fæces, and attached it to the walls of the abdomen. The patient was then placed in bed with artificial heat around him, and was given stimulants by the rectum and hypodermically. He was also given aromatic spirit of ammonia, digitalis, and nitrite of amyl. Although the operation did not occupy more than eighteen minutes, it was for some time a grave question whether he would rally at all. In a few hours he became conscious, expressed himself as greatly relieved, and at the end of twelve hours warmth returned in the extremities, with all the other evidences of good reaction.

The fistulous opening continued to discharge freely liquid yellow fæces. A milk diet was given at first, but as it seemed to pass somewhat quickly from the opening solid food was ordered. This, the patient stated, afforded him more satisfaction, and controlled his hunger.

He now rapidly improved, and gained in flesh, but no movement of the lower bowel could be obtained. On October 28th, an unsuccessful attempt was made to force water, *per rectum*, through the fistula.

November 1. Senn's apparatus for the injection of hydrogen gas was used. It acted well, but only the large intestines could be dilated. The dilatation ceased abruptly in the neighborhood of the ileo-cæcal valve.

I now determined to do a more thorough operation, and to find the point of obstruction and its nature, and then, if thought best, do an intestinal anastomosis. I made the incision to the right of the median line, about as we would for removal of the appendix, but extended it somewhat higher. I found strong adhesions implicating the ileo-cæcal region and a portion of the ileum. These were so firm that I thought it unwise to disturb them. I discovered that the portion of the small intestine that I had opened to form the fistula was very near the lower end of the ileum. I, therefore, thought it best to attach the loop nearest to, and just above the fistula, to the beginning of the ascending colon, which was done without much difficulty by means of Senn's bone-plates and Lembert's sutures. The portion of the ileum just below the fistula, together with the cæcum, was entirely collapsed, and with the adhesions, the appendix, etc., formed a dense mass. All this was "side-tracked" by the anastomosis. The wound was closed and dressed in the usual manner.

Patient rallied well. Pulse 100, full and strong. Fistula began to discharge eight hours after operation.

On the second day he complained of dyspepsia, and pain from the distended abdomen.

On the third day he passed gas, and a slight amount of fæcal matter *per rectum*. At 7 P. M., on this day three superficial stitches were removed. The wound looked well despite the fact that on two occasions the discharge from the fistula had run over the seat of operation. The wound was cleansed and painted with a solution of iodoform in collodion.

On the eighth and ninth day there was a slight fæcal discharge from the rectum. He took a small amount of general diet.

On the eleventh day an enema was followed by two solid movements. Fistula continued to discharge.

On the fourteenth day glycerin suppositories were given, and caused a large movement.

19th. An attempt was made to freshen the edges of the fistula, which had grown very small, yet discharged occasionally, very much to the annoyance of the patient. The operation was almost successful,

and was repeated on November 20th. The fistula then closed, so that his passages became natural.

The patient now began to worry about going home, whether he would be able to support his family, etc. He was apparently doing well, his appetite was good, and he slept well.

December 4. He began to show signs of restlessness, and while not complaining of pain in the abdomen, he suffered from severe pain which began in the left groin and darted down the thigh. There was also pain in the back. The left leg was cold, the posterior tibial artery could not be felt, and he had all the symptoms of arterial embolism. The limb was wrapped in warm applications. His temperature suddenly went up to 105°, and the pulse to 150. Stimulants by the mouth and rectum and hypodermically were employed. He continued restless, passed into a condition of collapse, became delirious, and died on the 5th at 2 A. M.

Autopsy: Rigor mortis not marked; body emaciated; the recent wound in good condition. Abdomen opened in the line of the old fistulous wound. About one drachm of pus was found at the most dependent portion of the last wound for closing the fistula. No recent peritonitis, but evidences of old peritonitis. Extensive adhesion of intestines among themselves, and to the abdominal wall on the right side. The portion of the intestines where the anastomosis had been performed was removed, and union was found to be perfect. The opening connecting the intestines admitted the end of the little finger. Bone-plates entirely absorbed. All the other organs apparently healthy.

This case has caused me much thought. I am convinced that had I attempted any more prolonged operation at the time he was brought in he would have died on the table. Who will deny that his chances in an operation would have been decidedly better had he been seen in consultation in the early part of the attack? What can we do in such cases, in which, when we are called, the conditions of shock and collapse are so decided? This case also impresses us with the danger of repeated irritations of an old hernia. Adhesions will form, and are often present when we least expect them. Consider, however, that the adhesions were on the side opposite to that of the hernia.

Case VI.—Mrs. G. H., aged thirty years, married at the age of eighteen years, and the mother of five children. She began to menstruate when twelve and a half years old, and was regular from that time until her first pregnancy, which occurred two months after marriage. She then had four children in rapid succession. Her first child weighed nearly twelve pounds, and the labor was somewhat tedious. She states that she took large quantities of ergot, and that her pains at the end of the confinement were very severe.

The patient first came under my care in June, 1883, for uterine trouble. Previously a plump, handsome girl, she now had the anxious expression and the general appearance of much past suffering.

I found a laceration of the perineum, a badly-lacerated cervix, and the uterine appendages much thickened and very sensitive. The uterus was much enlarged and completely retroverted, cervix swollen and tender, with the evidences of pelvic peritonitis.

The usual hot-water treatment, local scarification of the cervix, tampons of glycerin, and rest were employed. The diet and bowels were carefully regulated. After four months' treatment she began to improve, but at this time her children sickened and two of them died, which depressed her very much. Later her treatment was renewed, and when the local tenderness and inflammation had sufficiently subsided I made an effort to have her wear a suitable pessary, but this instrument always did more or less harm.

During the latter part of 1885 she began to have quite severe hæmorrhages. Her menstruation would begin gradually, then come in gushes, and exhausted her very much. There were no evidences of a tumor. I curetted the uterus thoroughly, and brought away considerable granular detritis, which was followed by a decided improvement in her symptoms.

Again an attempt to wear a pessary was made, but the result was not encouraging. She had now at her home a very intelligent family physician, and as there had been some return of the hæmorrhage in May, 1886, I advised him to curette the uterus, and to get along as well as possible without the pessaries. This treatment was carried out and she did improve somewhat, so much so that in April, 1887, I operated on the laceration of the cervix. This was followed by an improvement in all her symptoms. Just previously to this operation she acquired the morphine-habit, which was very difficult to overcome.

About three months after the operation she began to show symptoms of a tapeworm. This caused much mental depression, but medicine finally expelled the tænia.

After this she had more hæmorrhage, and was curetted again, with excellent results. The uterus remained in good position, and was nearly normal in size. Soon after, she became pregnant, which caused great depression and a return to the secret use of morphine or codeine. The infant was born in August, 1888. She had the best of care and did well, but after the puerperium her strange actions disturbed her physician and friends. It was evident that she was taking anodynes. She frequently made costly and unnecessary purchases, and at public gatherings she had one or more seizures in which she became unconscious.

Her physician and husband again consulted me as to what had best be done. I advised that she be sent to some private hospital, and an effort was made to place her under the treatment of Dr. S. Weir Mitchell, but owing to his absence this was found impossible. At last she was brought to the Albany Hospital, where we succeeded in stopping the anodynes.

During the previous six months she had been irregular in her menstruation and suffered much. On examination I found the tubes thickened, the ovaries very sensitive, and the uterus markedly re-

troverted. After consultation, and with the full and earnest endorsement of her husband, it was thought wise to make an abdominal exploration, discover the true condition of the appendages, and, if necessary, to remove them, bring the uterus into position, and attach it to the abdominal walls. In view of the supposed diseased condition of the tubes I did not approve of doing the Alexander operation.

October 30, 1889. The patient being in the best condition mentally that I had seen her in for months, and much improved physically, after proper preparation, assisted by my calleagues, I operated. Pyosalpinx was found. One ovary was cirrhosed, the other very much enlarged and in a condition of cystic degeneration. The pampiniform plexus on each side was enormously enlarged. The appendages were included in the Staffordshire knot, and removed in the ordinary way. I did not have much trouble in bringing the uterus into position and attaching it to the under surface of the abdominal wall in front, but this was a fatal step in the operation, as the result will show.

The operation was done at 11 A.M., and occupied about half an hour. There was no hæmorrhage of importance, though I tore a considerable number of adhesions on the left side. In closing the wound no drainage-tube was introduced.

I left her at noon, fully recovered from the operation, and expressing herself as feeling very comfortable. At 1 o'clock I found her sleeping, and apparently comfortable, but she looked pale and her pulse was rapid and weak. I suspected hæmorrhage, and opened the lower end of the wound, when a flow of blood told but too well what was going on. I immediately opened the incision and found that the ligatures had failed to hold the large veins, from which a serious hæmorrhage had occurred, filling the pelvis and extending up into the abdomen. With the assistance of Dr. Townsend, we secured, after much effort, the bleeding vessels, but our patient was moribund. Rectal injections of hot whiskey were employed, and warm milk was injected into the median basilic vein, but all did little good, and at 3 P. M. she was dead.

My reflections on this case have been of the saddest. I think that we undertook too much; at least I should have secured the plexus of veins in sections when fastening the uterus in position. It may be said that the house physician, who was in charge, as well as the experienced nurse who was present, ought to have discovered the patient's condition and reported at once to me; but she was so comfortable as entirely to disarm them.

Case VII.—Mrs. M. E. N., aged forty-five years, widow; admitted to the hospital, May 6, 1890. Family history good. Patient was well and strong up to twenty years of age, when she was treated for "womb trouble." Since then she has taken more or less medicine.

Menstruation began at the age of thirteen years. At times it was painful, and the quantity irregular. She married at the age of twenty-two years, but has had no children or miscarriages. Never had any acute disease, and always worked hard. Between seven and eight years ago, after having had vague, indefinite symptoms for some months, she noticed a hard, round bunch low down in the abdomen. When first seen this was the size of a cocoanut, but increased and now fills the abdomen, spreading out in all directions. The tumor is hard and dense, but never caused severe pain. Patient has lost strength, but not flesh. Menstruation unchanged. Bowels regular. She urinates a little more frequently than is natural.

She came to the hospital saying that she was unable to work and was anxious to have the tumor removed. When told that it implicated the whole uterus, and that if an operation was done all would have to be removed, she replied: "I cannot live long as I am; I will take all the risk; you do the operation."

The tumor was movable, yet presented so formidable an appearance that I declined to operate, and for two months made use of electricity and ergot, the tumor constantly increasing. It became such a burden as to make it almost impossible for her to get about, and on June 23d, I did a supravaginal hysterectomy. I was obliged to make an incision from the ensiform cartilage to the symphysis pubis, but found no adhesions. Using a corkscrew I lifted the tumor directly out of the abdomen, but was distressed to observe enlarged veins, as in the previous case. I placed around the neck of the tumor Tait's rope écraseur, isolated and tied the veins in sections, and removed the tubes and ovaries separately. I then removed the uterus with the tumor. The pedicle formed was about half the size of my wrist. I at first endeavored to control the hæmorrhage with a Staffordshire knot, but this was not sufficient. I then tied the vessels separately as they appeared in the stump, and tied the stump in sections by the lock-stitch. I then brought together the peritoneum over the stump and broad ligament, shutting the latter out from the peritoneal cavity. Silk alone was used for the ligatures and sutures. A long, glass drainage-tube was introduced well down in the cavity of the pelvis at the lower end of the incision, and the longest incision that I have ever made was closed in the usual way.

For five days there was a free, bloody discharge from the tube; after that only stained serum. The tube was removed on the twelfth day. On the twenty-first day her temperature ran up and indicated pus-formation. Examination on the next day confirmed what the nurse suspected during the night, namely, that an abscess had empted into the vagina. Vaginal douches were used daily, and a careful watch kept up for escaped ligatures, but none were found. Aside from the abscess the patient made an uninterrupted recovery.

PEROXIDE OF HYDROGEN AND OZONE.[1]

BY PAUL GIBIER, M.D.,
DIRECTOR OF THE PASTEUR INSTITUTE OF NEW YORK.

Since the discovery of peroxide of hydrogen by Thenard, in 1818, the therapeutical applications of

[1] Read before the International Medical Congress, Berlin, August 7, 1890.

this oxygenated compound seem to have been neglected both by the medical and the surgical professions; and it is only in the last twenty years that a few bacteriologists have demonstrated the germicidal potency of this chemical.

Among the most elaborate reports on the use of this compound may be mentioned those of Paul Bert and Regnard, Baldy, Péan, and Larrivé.

Dr. Miguel places peroxide of hydrogen at the head of a long list of antiseptics, and close to the silver salts.

Dr. Bouchet has demonstrated the antiseptic action of peroxide of hydrogen when applied to diphtheritic exudations.

Professor Nocart, of Alfort, attenuates the virulence of the symptomatic microbe of carbuncle, before he destroys it, by using the same antiseptic.

Dr. E. R. Squibb,[1] of Brooklyn, has also reported the satisfactory results which he obtained with peroxide of hydrogen in the treatment of infectious diseases.

Although the above-mentioned scientists have demonstrated by their experiments, that peroxide of hydrogen is one of the most powerful destroyers of pathogenic microbes, its use in therapeutics has not been as extensive as it deserves to be.

In my opinion, the reason for its not being in universal use is the difficulty of procuring it free from hurtful impurities. Another objection is the unstableness of the compound, which gives off nascent oxygen when brought in contact with organic substances.[2]

Besides the foregoing objections, surgical instruments decompose the peroxide; hence, if an operation is to be performed, the surgeon uses some other antiseptic during the procedure, and is apt to continue the application of the same antiseptic in the subsequent dressings.

Nevertheless, the satisfactory results which I have obtained at the Pasteur Institute of New York, with peroxide of hydrogen, in the treatment of wounds resulting from deep bites, and those which I have observed at the French clinic of New York, in the treatment of phagedenic chancres, varicose ulcers, parasitic diseases of the skin, and also in the treatment of other affections caused by germs, justify me in adding my statement as to the value of the drug.

But it is not from a clinical standpoint that I now direct attention to the antiseptic value of peroxide of hydrogen. What I now wish is merely to give a full report of the experiments which I have made on the effects of peroxide of hydrogen upon cultures of the following species of pathogenic microbes: bacillus anthracis, bacillus pyocyaneous, the bacilli of typhoid fever, of Asiatic cholera, and of yellow fever, streptococcus pyogenes, microbacillus prodigiosus, bacillus megaterium, and the bacillus of osteomyelitis.

The peroxide of hydrogen which I used was a 3.2-per-cent. solution, yielding fifteen times its volume of oxygen; but this strength was reduced to about 1.5 per cent., corresponding to about eight volumes of oxygen, by adding the fresh culture containing the microbe upon which I was experimenting. I have also experimented upon old cultures loaded with a large number of the spores of the bacillus anthracis. In all cases my experiments were made with a few cubic centimetres of culture in sterilized test-tubes, in order to obtain accurate results.

The destructive action of peroxide of hydrogen, even diluted in the above proportions, is almost instantaneous. After a contact of a few minutes, I have tried to cultivate the microbes which were submitted to the peroxide, but unsuccessfully, owing to the fact that the germs had been completely destroyed.

My next experiments were made on the hydrophobic virus in the following manner:

I mixed with sterilized water a small quantity of the medulla taken from a rabbit that had died of hydrophobia, and to this mixture added a small quantity of peroxide of hydrogen. Abundant effervescence took place, and, as soon as it ceased, having previously trephined a rabbit, I injected a large dose of the mixture under the dura mater. Slight effervescence immediately took place and lasted a few moments, but the animal was not more disturbed than when an injection of the ordinary virus is given. This rabbit is still alive, two months after the inoculation.

A second rabbit was inoculated with the same hydrophobic virus which had not been submitted to the action of the peroxide, and this animal died at the expiration of the eleventh day with the symptoms of hydrophobia.

I am now experimenting in the same manner upon the bacillus tuberculosis, and if I am not disappointed in my expectation, I will be able to impart to the profession some interesting results.

It is worthy of notice that water charged, under pressure, with fifteen times its volume of pure oxygen has not the antiseptic properties of peroxide of hydrogen. This is due to the fact that when the peroxide is decomposed nascent oxygen separates in that most active and potent of its conditions next to the condition, or allotropic form, known as ozone. Therefore it is not illogical to conclude that ozone is the active element of peroxide of hydrogen.

[1] Gaillard's Medical Journal, March, 1889.

[2] The peroxide of hydrogen that I use is manufactured by Mr. Charles Marchand, of New York. This preparation is remarkable for its uniformity in strength, purity, and stability.

Although peroxide of hydrogen decomposes rapidly in the presence of organic substances, I have observed that its decomposition is checked to some extent by the addition of a sufficient quantity of glycerin; such a mixture, however, cannot be kept for a long time, owing to the slow but constant formation of secondary products having irritating properties.

Before concluding I wish to call attention to a new oxygenated compound, or rather ozonized compound, which has been recently discovered and called "glycozone" by Mr. Marchand.

This glycozone results from the reaction which takes place when glycerin is exposed to the action of ozone under pressure—one volume of glycerin with fifteen volumes of ozone produces glycozone.

By submitting the bacillus anthracis, pyocyaneous, prodigiosus, and megaterium to the action of glycozone, they were almost immediately destroyed.

I have observed that the action of glycozone upon the typhoid-fever bacillus, and some other germs, is much slower than the influence of peroxide of hydrogen.

In the dressing of wounds, ulcers, etc., the antiseptic influence of glycozone is rather slow if compared with that of peroxide of hydrogen, with which it may, however, be mixed at the time of using.

It has been demonstrated in Pasteur's laboratory that glycerin has no appreciable antiseptic influence upon the virus of hydrophobia; therefore I mixed the virus of hydrophobia with glycerin, and at the expiration of several weeks all the animals which I inoculated with this mixture died with the symptoms of hydrophobia.

On the contrary, when glycerin has been combined with ozone to form glycozone, the compound destroys the hydrophobic virus almost instantaneously.

Two months ago a rabbit was inoculated with the hydrophobic virus which had been submitted to the action of this new compound, and the animal is still alive.

I believe that the practitioner will meet with very satisfactory results with the use of peroxide of hydrogen, for the following reasons:

1. This chemical seems to have no injurious effect upon animal cells.

2. It has a very energetic destructive action upon vegetable cells—microbes.

3. It has no toxic properties; five cubic centimetres injected beneath the skin of a guinea-pig do not produce any serious result, and it is also harmless when given by the mouth.

As an immediate conclusion resulting from my experiments, my opinion is, that peroxide of hydrogen should be used in the treatment of diseases caused by germs, if the microbian element is directly accessible; and that it is particularly useful in the treatment of infectious diseases of the throat and mouth.

STUDIES IN THERAPEUTICS: BERBERIS AQUIFOLIUM.

By JOHN AULDE, M.D.,

MEMBER OF THE AMERICAN MEDICAL ASSOCIATION, OF THE MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA, OF THE PHILADELPHIA COUNTY MEDICAL SOCIETY, ETC., PHILADELPHIA.

Notwithstanding the glowing reports which appeared more than ten years ago in such journals as the *Therapeutic Gazette*, relating to the valuable properties of this drug, but little progress has been made by it toward a permanent place in our materia medica. True, it is one of the important ingredients of the preparation known as Cascara Cordial, and enters into the composition of the compound syrup of red clover (Syr. Trifolium Compound), but at present it does not occupy a position which is well adapted to promote its general use. The literature upon this subject which I have lately examined (*Pharmacology of the Newer Materia Medica*, George S. Davis) appears to be more highly colored than the qualities of the drug warrant, although I have no doubt that excellent results followed its use in the hands of those who estimated its clinical position ten or more years ago. My own experience with the drug covers a period of several years in private and in dispensary practice, and my estimate will be based upon my own work and clinical observations; although, of course, I have been guided in its administration by the reports of others, to whom I desire to give proper credit, although I cannot mention their names, nor can I attempt to enter upon a discussion of the claims which have been put forward in regard to the action of the drug in the numerous classes of cases treated.

Inasmuch as this remedy is comparatively a new one to many younger practitioners, it is advisable to give some information in regard to the source and character, together with a brief reference to the physiological actions of the drug.

Berberis aquifolium (Pursh), variously known as holly-leaved barberry, mountain grape, and Oregon grape-root, belongs to the natural order Berberidaceæ, and is found on the Pacific slope of the United States. At least one of the active principles is an alkaloid, berberine, which exists in other plants also, and occurs in the form of an amorphous powder, soluble in hot water and alcohol, but insoluble in ether. In addition to this alkaloid the plant contains resins, and when the fluid extract is combined with water, the water should first be rendered alkaline, else the alkaloid will be precipitated. The dose of the fluid extract, which is the product I

have investigated, ranges from 5 to 20, or even 30 drops three times daily; and, as a rule, it is best dispensed in combination with a little glycerin or an alcoholic preparation. A discussion of berberine, the alkaloid, properly belongs to the study of Hydrastis canadensis.

Pharmacology.—The taste of preparations containing berberis alone is that of a simple bitter, but it is not especially disagreeable; to the writer it resembles very much the taste of the bark of fresh elders, such as boys use in making whistles. It is far less objectionable than either nux vomica or cinchona preparations, and can readily be given to children. Taken into the mouth it has the effect of slightly increasing the flow of saliva, but small doses cause no burning sensation in the stomach. When ingested with food, or shortly after, the flow of gastric juice is augmented, if we may judge by the increased activity of the digestion under those conditions, and a stimulating effect appears to be produced throughout the alimentary tract. My impression is, that in some cases through its influence upon the intestinal glands, a more healthy condition is established, owing to the more rapid elimination of waste-products.

The character of the cases in which it is used with curative effect would lead to the supposition that berberis is an active agent in promoting tissue-change. This may possibly be due to the lack of actively poisonous properties, such, for example, as those that we find in nux vomica; certainly the exhibition of moderately small doses produces effects which are extremely satisfactory in the treatment of numerous affections, and I am inclined to believe that these beneficial effects are largely due to the eliminative properties of the drug acting upon the liver and the kidneys, and to its stimulating action upon the glandular appendages of the intestine. Still, it cannot be regarded as a drug which has a depressing action upon the organism; on the contrary, the general action of berberis, when taken for a considerable time (one or two weeks), is practically that of a tonic.

Its *antagonists* include astringents and remedies which depress the system or interfere with digestion. Its *synergists* may be said to embrace all drugs and remedial agents which improve the general tone, whether they accomplish this by a process of rebuilding, as iron and arsenic, or by causing the elimination of poisonous or diseased materials, as in the case of iodine and mercury.

Unlike nux vomica, cinchona, and simple bitters generally, berberis produces an effect upon the system which is, as a whole, excellent, although apparently not marked. After medicinal doses no changes occur in the circulation or in the temperature of the body. Respiration remains unchanged, and the general effect upon the muscular system appears to be that of a tonic. The beneficial effect upon the digestive system, the blood, and the secretions, is quite perceptible. If there is constipation the movements of the bowels become more regular, and, with appropriate regulation of the diet, the stools become of good consistence and color, an influence which the blood quickly feels. The consequences are that the complexion clears, muscular strength is augmented, and along with a slight increase in the activity of the urinary organs and the skin, berberis may be said to be an ideal alterative. That it is an important alterative, I have the best evidence; but that it will take the place of others I doubt, although combinations can be made with berberis as an ingredient which will surpass many of the products in use at the present time. In looking at the alterative action we must not forget that a remedy, to be alterative, must act as a tonic; and to act in this manner it must be laxative, diuretic, and diaphoretic—properties which are characteristic of the drug under consideration to a degree sufficient to warrant its more general use by members of the profession in general practice.

Therapeutics.—For convenience it is desirable to study the applications of the remedy in the treatment of disease by grouping the different affections in which the drug may be used with the expectation of obtaining good results. First upon the list should be indicated that class known as the "blood diseases," which includes syphilis and scrofula. In each of these diseases the remedy has been highly extolled, although I cannot speak from personal observation of its value in the former. With attention to diet and hygiene, and alternated with other drugs which may be classed as hæmatinics, I have seen remarkably good results follow the use of berberis in scrofulous disorders, and even in cases with a tendency toward scrofula. The general practitioner will, of course, understand that no one remedy is sufficient to overcome the diathesis in these cases, but I fully believe in the utility of berberis in restoring the functions to their normal condition.

In my experience, which has been comparatively limited, not having used the drug in more than twenty-five cases of various disorders, the best results have followed its use in the treatment of derangements of the alimentary tract, with or without constipation. The symptoms calling for its exhibition are very much the same as those which are so well known as indicative of indigestion, namely, coated tongue, fœtid breath, and a general feeling of malaise, with little or no appetite. The special indications, however, which I have thought demanded berberis, may be summarized as follows: Long-continued gastric and intestinal indigestion,

not very severe, but occasionally lighted up by some indiscretion of diet or exposure to inclement weather, or over-exertion. The patient has become thin, but not emaciated, and does not suffer much inconvenience from constipation, although there may be slight rectal irritation from hæmorrhoids. If the patient be a woman all these symptoms will be more distinct than if a man, and in addition there may be some uterine trouble. This complication is very common about the climacteric, but it in no-wise forms a contraindication to the use of the drug. The following case will illustrate this fact more fully:

Mrs. S. is, for all practical purposes, an invalid, having been under treatment for about two years, and during three or four months she has been confined to her bed. She is now forty-two years old, and her eldest child is aged thirteen years. She has passed through the hands of four physicians during her illness. There is decided derangement of all the functions, and she has become very much depressed physically. Brooding night and day over her misfortunes has caused her to suffer occasionally from melancholy, and she thinks it would be impossible to live had she not access to a bottle of medicine containing chloral and bromide, which her last physician prescribed for her. In order to avoid any complications which might arise from having two kinds of medicine, I scratched off the label from the bottle containing the anodyne mixture. As I did not purpose giving her any medicines of that nature I thought that that was the best method of "tapering off."

Beginning in the mouth, this patient had some derangement of the whole alimentary tract. She suffered from stomatitis, from dyspepsia, from fermentation of food in the intestines, from obstinate constipation, and from hæmorrhoids. In addition, there were more or less ovarian pain and tenderness, almost constant headache, and cardiac irritability.

The treatment consisted in regulating the diet, and prescribing remedies for the purpose of removing the most conspicuous symptoms, and in the course of a few weeks she was sufficiently improved to be placed on tonic treatment, the most active constituent of which was fluid extract of berberis aquifolium, 20 drops three times daily.

This patient first came under observation during the past winter, and as a result of the final prescription, containing berberis, she gained so much that treatment was discontinued at the end of two months. Since then she has gone to housekeeping, and through patients whom she sends me from time to time I learn that she is quite as well as she has been at any time for many years.

Another patient, a woman of more than sixty years, who had long resided in a malarious section in the South, consulted me about the same time as the preceding case, and was placed on berberis after anti-malarial treatment had arrested the disease. A few weeks only were required to correct the ailments which had been brought about by the malarial complication.

A favorite formula with me is the following:

R.—Fluid extract of berberis aquifolium . . . . } of each, ½ ounce.
Glycerin . . . . }
Tincture of prickly ash with Jamaica rum, 4 ounces.
Dose, a tablespoonful in water after meals.

Both xanthoxylum and berberis possess valuable antiperiodic properties, and when we have to contend with complications the appropriate remedies will readily suggest themselves. Thus, when we have to deal with a torpid condition of the liver, podophyllum, or euonymus will be considered, while if there be constipation some preparation of aloes, or, preferably, cascara, will be indicated. When a diuretic influence is sought, small doses of hyoscyamus may be added, and in cases of marked debility nux vomica will be the proper remedy. Occasionally it will be found that a special cardiac tonic is demanded, and in such cases strophanthus should be used. I recall a case of this character which occurred during my connection with the Medico-Chirurgical Hospital, which illustrates in a striking manner the value of the latter drug.

A drayman, aged sixty-one years, had suffered for a long time from general weakness and loss of appetite. He had been treated for nervous prostration, for senile heart, and for fatty degeneration of the heart, but no improvement had attended the efforts of his physicians. Upon examination I decided that he was suffering from the effects of tobacco-poisoning and from gastro-intestinal catarrh, and prescribed for him 5 drops of the tincture of strophanthus with 20 drops of the fluid extract of berberis aquifolium and a little syrup of rhubarb, to be taken after meals three times daily. In a week he was improving so rapidly that no change was made in the treatment.

Through the kindness of Messrs. Parke, Davis & Co. a quantity of the drug was placed at my command in the dispensary, and was used with good results in a large number of cases.

The treatment of chronic rheumatism by the exhibition of the foregoing combination is in many cases rewarded by permanent relief, and it is also efficient in all glandular enlargements and in chronic hepatitis.

In the treatment of numerous skin affections, especially those of the scaly variety, along with appropriate diet and local measures, berberis will often prove effective when other approved methods of treatment fail to afford more than temporary relief.

By ridding the system of objectionable material, stimulating the activity of the glandular system and promoting digestion, berberis becomes a valuable aid in the treatment of various forms of phthisis, when the disease is not too far advanced. By relieving the congestion of the pelvic viscera, and

keeping the bowels in a healthy condition, it answers a valuable purpose in the treatment of diseases incident to women, and with the addition of the tincture of prickly ash, there are few of such cases that will not be decidedly benefited by the use of berberis.

1910 Arch Street.

VAGINAL LITHOTOMY.

By ROBERT REYBURN, M.D.,

Professor of Physiology and Clinical Surgery in the Medical Department of Howard University, Washington, D. C.

On May 5, 1888, I saw at my office, in consultation with Dr. Seifritz, Mrs. R., aged thirty-two years, white, and the mother of two children.

The patient had suffered for nearly two years before coming under the care of Dr. Seifritz from irritation of the urinary bladder and other symptoms which had been, by the several physicians who attended her, attributed to uterine disease.

Dr. Seifritz, on making a careful examination, had discovered a calculus in the bladder, and believing it to be of moderate size we determined to attempt its removal *per urethram*.

The patient was placed under the influence of chloroform and the urethra was fully dilated, so that the index finger could be introduced, and the bladder thoroughly explored. The calculus was readily found, and an attempt was made by long forceps to remove it from the bladder through the urethra, but it was too large to be removed in this way without great danger of lacerating the canal.

Dr. Bigelow's admirable apparatus for crushing and removing the stone not being at hand, I determined to remove it through the vagina. Introducing the forefinger of the left hand into the bladder through the urethra, the calculus could be plainly felt, and drawing it downward I pressed it firmly against the lower surface of the bladder, when I could feel it impinging upon the roof of the vagina. Keeping my forefinger pressed upon the calculus I made an incision about two inches in length through the roof of the vagina and coats of the bladder, directly upon the calculus, and thus removed it.

The operation was a simple one, and as easy as the opening of an ordinary abscess. Silver sutures were inserted so as to coapt accurately the edges of the wound, and were passed through the roof of the vagina, also including the walls of the bladder. After rallying from the operation the patient was sent to her home in a carriage.

The temperature on the day following the operation reached 102°, but after a few doses of antipyrin it fell to normal, and remained so.

The after-treatment consisted of washing out the bladder morning and evening with a one-per-cent. solution of boric acid.

For two weeks after the operation the patient suffered from incontinence of urine, due to the dilatation of the urethra, but this gradually lessened, and three weeks later the symptom had entirely disappeared. The sutures were removed on the twelfth day, and at that time the incision had entirely closed.

One month after the operation the patient was well, and has continued so.

The calculus was of the phosphatic variety, weighed 2 drachms and 20 grains, and measured one inch in its short diameter and one and a quarter inches in its long diameter.

Of course, it is hardly necessary to say that under ordinary circumstances the proper treatment of such a case would be litholapaxy. In a limited number of cases, however, the operation of vaginal lithotomy is useful, and is one of the easiest operations in surgery.

Professor E. L. Keyes[1] says:

"The operation is safe and successful. The mortality, according to Aveling's statistics, collected in 1864, is about three per cent.—one out of thirty-five cases. Vidal had thirty cases without a death, but complained that fistula often followed. Agnew credits forty-eight operations to American surgeons, with two deaths. In both these cases the stone was very large."

It will be seen, therefore, that the mortality of this operation is less than that of any of the other operations for stone.

The danger of the operation is the formation of a permanent vesico-vaginal fistula. My own belief is that this will rarely or never occur if the bladder is fairly healthy, and if irrigation with boric acid or other antiseptic is used.

APPENDICITIS PERFORATIS.

By L. SCHOOLER, M.D.,

Professor of the Principles and Practice of Surgery and Clinical Surgery in the Iowa College of Physicians and Surgeons, Des Moines, Iowa.

Appendicitis is caused by foreign bodies or concretions of fæcal matter entering the appendix, the orifice of which is uniformly smaller than the canal itself. In health small portions of fæcal matter enter and escape from the appendix without causing irritation, and possibly foreign bodies, such as cherry-stones, seeds, etc., occasionally do the same, though the larger, firmer, and more irregular bodies are less likely to escape. When retained, they excite a catarrhal inflammation of the mucous membrane, which has the effect of still more tightly closing the only opening by which escape is possible. Suppuration and ulceration follow, and may cause perforation.

The symptoms of perforation are not always well defined. Those pertaining to the acute termination of the disease are the most distinct, and consist of sudden collapse, shock, or intense pain, with the sudden occurrence of all the symptoms usually present in violent forms of peritonitis. In this method of termination the pus is poured directly into the abdominal cavity. If there is chronic inflammation the symptoms will correspond to the

[1] International Encyclopædia of Surgery, vol. vi. p. 298.

character of the inflammation, and if there is burrowing of pus, as described by some authors, the symptoms may be so obscure that great difficulty is experienced in arriving at a conclusion as to the exact origin of the inflammation.

While the latter method of termination has been described, its occurrence is extremely doubtful. All descriptions of the symptoms and progress are very unsatisfactory, on account of the lack of positive proof that pus burrows under the pelvic fascia.

The most frequent termination, or rather a process which admits of a termination in the hands of the surgeon, is the one in which the inflammation of the tissues surrounding the appendix is of the constructive variety. In this variety a tumor can usually be discovered in the right iliac region; the appendix is firmly attached to the abdominal parietes; there is circumscribed peritonitis; the inflammation has advanced before the suppuration, and the exudate is abundant and completely encapsulates the collection of pus. In this form the appendix will be found in the centre of the pus-cavity in a state of either acute or gangrenous inflammation. There will also be found a perforation midway between the two extremities of the organ, and frequently, perhaps in one-half of all cases, the foreign body or fæcal concretion may be found. Careful examinations in the future will undoubtedly greatly increase the number of cases in which these bodies may be found.

Great confusion exists with reference to all inflammations of the right iliac region, owing to the indefinite or meaningless terms, *typhlitis*, *perityphlitis*, and that added by Musser, *paratyphlitis*. The first is supposed to indicate an inflammation of the cæcum, the second an inflammation of the connective tissue posterior to the appendix, and the third an inflammation of the walls of the appendix. The first is objectionable because meaningless—*cæcitis* is more definite, and is anatomically correct. The second, *perityphlitis*, is not applicable unless the connective tissue exists, which is not admitted by anatomists. The third, *paratyphlitis*, is used to indicate an inflammation of the walls of the appendix, and were it not for the fact that the inflammation always has its origin in the interior, and involves the mucous membrane, the term might be of some value. In the present state of pathological knowledge, and in view of the fact that the appendix is an organ subject to characteristic diseases, a nomenclature based upon anatomical considerations is certainly preferable to the old terms that have given rise to so much confusion, and have confounded colitis and cæcitis with appendicitis.

When the collection of pus is small the difficulties of diagnosis may be great, and in some instances percussion may give increased resonance rather than dulness. When the disease is chronic, there may remain for a long time a small amount of pus, with no tendency for the sac to rupture. In such cases the collection may amount to a pint or more.

Even though the last method of termination is greatly to be desired, it is not free from dangerous complications. The originally circumscribed inflammation of the peritoneum may become general, and if treatment is unduly postponed, obstruction of the bowels may occur. The following case is cited in illustration:

On September 8, 1888, I was requested by Dr. Charles H. Plunket to see H. W., male, aged eight years, who was said to be suffering from intestinal obstruction. I found him complaining of paroxysmal attacks of pain, and occasionally vomiting small amounts of fluid. The pulse was 120, and temperature normal. He was sleepless, though morphine had been freely administered. The abdomen was tympanitic and countenance somewhat anxious. Dr. Plunket's diagnosis was confirmed, although the pain in the right iliac region caused a suspicion of appendicitis—in fact, the history was that the patient had returned from school three days previously on account of pain in that region. The abdomen was too much distended and tender to permit of a very careful examination.

I saw him again on September 9th, when his condition was the same, except that there was general peritonitis. I advised anæsthesia for the purpose of diagnosis, which was consented to. A small tumor was discovered in the right iliac region, and also fulness on the left side, which was most apparent to the touch *per rectum*.

Appendicitis, and general peritonitis, with obstruction, was diagnosed, and abdominal section advised. I saw the patient again, September 10th, when there was no change, except that he was more exhausted than on the previous day.

Operation, September 11: Chloroform being administered, an incision three inches in length was made in the median line, which permitted a considerable quantity of fluid to escape. Two fingers introduced into the cavity readily detected extensive adhesions, and a small tumor at the site of the appendix, adherent to the abdominal wall. Although the manipulations were gentle, the wall of the sac ruptured, and about two ounces of foul-smelling pus escaped into the abdomen. The appendix was found to be ruptured in the middle, and was at once tied off. Further examination revealed firm, adhesive bands just above the cæcum, causing complete obstruction. These were broken with the fingers, and the ragged edges trimmed with scissors. A similar condition was found at the sigmoid flexure on the left side, and the same means were adopted for the relief of the obstruction. When these bands were severed there immediately escaped from the rectum a large quantity of fluid fæcal matter, which was estimated at thirty-two ounces, while the escape of flatus was very free.

The small intestines were bound together throughout their entire extent, the inflammatory exudate

being abundant, but not firm. As there were no evidences of further obstruction the intestines were not disturbed. The cavity was thoroughly irrigated with water at a temperature of 110° F., until, apparently, all pus was removed, a drainage-tube was then inserted, and the wound closed. The discharge through the tube was slight, and had entirely ceased at the end of forty-eight hours. The tube was then removed, and the patient made a good recovery.

Antiseptic precautions were taken at every step of the procedure. In washing out the abdominal cavity, water that had been boiled and filtered three times was used.

The median incision in this case was certainly the best, as it permitted a thorough exploration of the abdominal cavity, and the easy manipulation of the adhesive bands for the relief of the obstructions. In cases without obstruction or other complications an incision a little to the inner side of the prominence of the tumor is proper.

The rule applicable to other collections of pus is also applicable to this disease, viz., early evacuation. Aspiration has been favorably reported upon in some cases, but in these there must have been some cause other than a foreign body. No special after-treatment is required. If the entire abdominal cavity is opened, as in the above case, thorough irrigation and the insertion of a drainage-tube, preferably a glass one, are imperative. No antiseptic should be used in washing out the abdominal cavity.

If there is a tendency to gaseous distention of the bowels a saline cathartic is admissible. Pain will rarely be so intense as to require the use of opiates.

HOSPITAL NOTES.

ALOPECIA AREATA—RHUS-POISONING—DOUBLE SYPHILITIC INFECTION—SEBORRHŒIC ECZEMA.

Abstract of a Clinical Lecture delivered at the New York Post-Graduate Medical School.

By ROBERT W. TAYLOR, M.D.,
PROFESSOR OF DERMATOLOGY AND SYPHILOGRAPHY.

Case I.—The first case to which Dr. Taylor directed attention was one of alopecia of about a year's duration, in a woman with good general health. The disease formed a rather large heart-shaped patch on the occipital region and the vertex, and two smaller ones on the temporal region. The smaller spots had made their appearance during the last six months. The disease was rather more extensive on the left than on the right side.

The lecturer said that in this disease there are usually no prodromal symptoms, such as itching or anæsthesia. After a round patch has formed, other patches develop in the vicinity of the first, and then fuse together, often resulting in a large denuded area. But, in this case, there were little islets of apparently healthy hair left. As the process goes on, the patch will undergo a very perceptible atrophy, and the margins of such denuded areas are sufficiently thickened to be detected by the touch. Very often the entire scalp is ultimately involved and sometimes every vestige of hair disappears from the entire body. In these extreme cases, it is not uncommon to find also that the nails fall off.

The prognosis of these cases is a question of great interest, and there are several points to be considered:

1. The general nutrition of the patient. Hairs are epithelial structures, and their nutrition depends upon that of the whole body.

2. The duration of the disease. If the duration has been more than one year, the prognosis is not good; and when it has lasted for from three to five years, absolute baldness is almost inevitable.

3. The amount of atrophy of the skin. There is a peculiar color of the skin of these patches, not unlike that of an old billiard-ball. When an examination of the patch with a magnifying glass shows much atrophy, the prognosis is bad; and when the follicles are decidedly funnel-shaped, there is no possibility of the reproduction of the hair.

Dr. Taylor said that the nature of this disease has been a "bone of contention" for many years. Just at present, the theory of its parasitic origin is popular, and among those holding this view is von Schlen, who was the first to proclaim it, and Dr. Robinson, of New York, who claims that it is due to the development of some peculiar micrococcus in the deep lymph-spaces, causing so much inflammatory change that the hair-follicles atrophy. The neuropathic theory supposes that it is due to impaired innervation and consequent malnutrition of the hair. Some are more conservative, and believe that there are two distinct forms—one of parasitic and the other of neuropathic origin. Dr. Taylor thinks the neuropathic theory the most plausible one. Whatever may be the opinion of its origin, the profession in America is not yet quite prepared for the statement made by a recent French writer in regard to "prophylaxis"; for, in this country, there are no observations which would make us look upon the disease as in any way contagious.

Treatment.—On the ground that it may possibly be a parasitic disease, it is well to get rid of every nidus of contagion, so the hair, if practicable, should be cropped, the scalp thoroughly shampooed and cleansed, first with alkaline washes and afterward with a 1-to-1000 or 1-to-2000 solution of bichloride of mercury. The following lotion may be well rubbed into the scalp several times a day:

R.—Tincture of cantharides	.	1 ounce.
Tincture of capsicum	.	½ "
Water, sufficient to make	.	8 ounces.—M.

Two drachms of cologne water may be added to this mixture.

Later, it may be necessary to change the treatment, for these cases are very obstinate. The scalp may be blistered with cantharidal collodion, or with a mixture of half an ounce of oil of mustard and two ounces of sweet oil. Dr. Taylor said that he had tried electricity, but had found it utterly useless. Cod-liver oil and other tonics are often indicated.

Improvement will be shown by the appearance of lanugo; but these will, in turn, often fall out.

CASE II.—This patient was an Italian laborer, who had an abundant vesiculo-bullous eruption on the back of the fingers and hands, but not in the interdigital spaces. It was also abundant on the anterior and posterior aspects of the wrists, and about the penis and scrotum. It was evident that there was some local cause.

The patient had been working upon a railroad near New York, and, on questioning, the case was found to be one of poisoning by some species of poison-oak, which, even in midwinter, may give rise to such attacks of dermatitis. Dr. Taylor spoke of a very severe and persistent case of this kind which he had seen many years ago in the hospital, and which had been reproduced upon the patient, and upon one of the orderlies, with the dried twigs of this hardy shrub.

Treatment.—The first essential in the treatment of all cases of inflammation of the skin, such as acne, eczema, rhus-poisoning, is to secure thorough cleanliness. It is not sufficient to plaster the affected part with an ointment. Patients with ivy-poisoning usually have much pain and burning, and to relieve these symptoms the parts should be soaked in hot water made alkaline with a little borax. This application is very soothing. After the soaking, apply absorbent cotton thoroughly saturated with lead-and-opium wash. After two or three days, a little carbolic acid may be added. The vesicles will soon begin to dry up and form crusts, and then the employment of zinc ointment containing balsam of Peru and a little camphor for the pruritus, will be all that is required.

CASE III.—The next patient, an English woman, thirty-seven years of age, presented a history of unusual interest, on account of its rarity. Eleven years ago, there was an eruption on the body, followed by nocturnal headaches and slight alopecia. She is not definite as to the presence of a sore on the genitals. The eruption was followed by large ulcerating and serpiginous ulcers on the face, neck, and limbs, and by a syphilitic inflammation of the muscles of the right arm and leg, which crippled her for three years. This syphilitic process, which attacks the biceps, calf muscles, and the masseters, is a diffused inflammation of the connective tissue, and was first described by Notta. It causes an immobile contraction of the muscles, and is called syphilitic muscular contraction. The eruption left numerous large scars upon the body and extremities. Four years ago, she had a bubo in the right groin, which lasted four months. Seven months ago, she began to have pains in the arms and legs, and, five weeks later, an eruption appeared over the entire body, and still exists. About this time, headaches became severe, and there was much alopecia. She denies having had sexual intercourse for ten years until within about a year, but the hospital records show that, four years ago, she had a sore on the right labium minus. The present eruption first appeared as a papular and pustular syphilide, occurring even on the scars of the previous eruption. There is general glandular enlargement.

It is the rule to find only one attack of syphilis in a lifetime, but, like smallpox, measles, and various other infectious diseases, syphilis may occur more than once, although these exceptions are much more rare than in the other diseases mentioned. There are only about forty-four authentic cases of it on record, four of which were reported by Dr. Taylor. There have been, undoubtedly, very many more, but they were not recognized, or, if recognized, not reported. With our improved methods of treating syphilis, a cure is possible, and a person once cured is liable to a second infection.

CASE IV.—A baby, five months old, next claimed attention for a seborrhœic eczema, which first appeared about one month ago, on the leg, and had the appearance of an ordinary chafe. This was powdered and washed, as usual, until it developed into a genuine eczema. The head is covered with greenish crusts, and the eruption on the neck is oozing and of a decided salmon-color. There is a patch on the buttocks, which, if left untreated, will spread to the popliteal region. There is not so much thickening as in the other forms of eczema, and it oozes a gummy, greasy secretion.

Treatment.—Cleanliness is, of course, all-important. Next to this comes the diet, which, in this case, has been condensed milk. Good cow's milk, properly sterilized in Arnold's sterilizer, should be substituted. No internal medicine is required. Locally, for such a delicate skin, resorcin is better than sulphur. To cleanse the parts after the application of the ointment, wipe them with a lotion composed of one part of bay-rum and three parts of water. The ointment most suitable for this case is as follows:

R.—Resorcin		20 grains.
Powdered starch Oxide of zinc ointment	of each	2 drachms.
Petroleum ointment . . .		½ ounce.

The quantity of resorcin may be increased or diminished according to the amount of stimulation produced.

MEDICAL PROGRESS.

Irrigation of the Intestine in Dysentery.—DR. H. A. FAIRBAIRN (*Brooklyn Medical Journal*, October, 1890) gives unqualified praise to the treatment of dysentery by irrigation of the large intestine. To be of use, the enemata should be large and repeated every two, three, or four hours. The quantity of water should be, for an adult, about three or four pints, at a temperature of from 100° to 105°. If possible, the water should be distilled, or at least boiled.

Dr. Fairbairn has not found it necessary to use any medicament in the water. As to the instrument used, he prefers a handball-syringe, believing that the pressure from a fountain-syringe is dangerous. The author also suggests that in chronic dysentery the walls of the bowel may be so much weakened that unless the pressure is very slight rupture may occur.

Medical Treatment of Fractures.—DR. DE VABONA Y GONZALEZ DEL VAILLE, of Havana, discusses, in a graduation thesis, the advantage of prescribing phosphorus in various forms to patients suffering from fractures. He carried out a series of experiments on dogs and fowls, by breaking the femur by means of an osteoclast and dressing the limb in splints. He then divided the animals into two groups, to the first group administering phosphorus, to the second no drugs being given.

The results were that the callus was more abundant in animals treated with phosphide of zinc than in those treated with phosphide of calcium, or in those to which no phosphorus was given.

These results were confirmed by observations in the surgical wards of a hospital, where it was found that patients with fractures who took from one-eighth to one-fourth grain of phosphide of zinc daily made exceptionally good and rapid recoveries. The only unpleasant effects produced by this treatment were, that one out of the eighteen patients on whom it was tried suffered from slight diarrhœa, and in another the pulse became slow and hard.—*Lancet*, September 27, 1890.

Ectopic Gestation Occurring Twice in the Same Patient.—Mr. G Ernest Herman (*British Medical Journal*, September 27, 1890) reports the case of a woman upon whom he operated for a ruptured ectopic gestation in January, 1887, removing the right tube. She again came under his care in May, 1890, with a clinical history and with physical signs that indicated a second ectopic pregnancy. The abdomen was opened by an incision in the line of the former one and the remaining tube was removed and found to contain a fœtus about one-third of an inch in length. The clinical history indicated that pregnancy had lasted about three months, and the size of the fœtus showed that it died at about the end of the first month.

Treatment of Labor delayed by Rigidity of the Cervix.—Dr. W. S. Playfair, in a discussion by the Section of Obstetrics of the British Medical Association, said that in 1874 he had directed attention to the value of chloral in labor. Since that time he has used it constantly with the best results and without trouble from rigidity of the cervix. Under the use of this agent the pains become longer, steadier, and more efficient, and the patient falls into a somnolent condition, dozing quietly between the pains, which are not lessened or annulled, as is so often the case when chloroform is used. More important than all, the wild stage of excitement which is so frequent in cases of rigid cervix is calmed, to the relief not only of the patient, but of the practitioner. It is not necessary to administer large doses; fifteen grains, repeated in twenty minutes, by either the mouth or the rectum, produce an effect that usually lasts for several hours. Possibly a third dose may be required, but never more. Another good effect of this drug is that when the expulsive stage is reached, the patient being already in a state of partial anæsthesia, much smaller quantities of an anæsthetic are required than would otherwise be the case.

Dr. Playfair also referred to the use of quinine, which, he said, acts rather as a general stimulant and promoter of vital energy than as an oxytocic, but that in cases of labor with feeble, ineffective pains in the first stage, one or two doses of fifteen grains often have a marked effect in strengthening the pains.

Dr. Robert Bell said that the employment of strychnine in small doses for two or three weeks before labor has a wonderful effect in promoting uterine action. In labor delayed by rigidity of the cervix, although he has had good results from the use of chloral, he now uses tincture of gelsemium in from five- to ten-drop doses, repeated at intervals of twenty minutes.—*British Medical Journal*, September 27, 1890.

The Treatment of Syphilis by Calomel Plasters.—M. Quinquand (*Annales de Dermatologie et de Syphilographie*) recommends for the treatment of syphilis a plaster containing calomel and applied over the region of the spleen. The plaster is composed of diachylon plaster 300 parts, sublimed calomel 100 parts, castor oil 30 parts. The skin having been washed with soap, the plaster is spread on a piece of muslin about four inches square and applied. It is removed at the end of eight days, and after eight more days is again applied and is allowed to remain for the same length of time. This process is repeated indefinitely. In the case of patients who are engaged in manual labor, the plaster should be renewed in four or five days after being removed.

M. Quinquand has assured himself, by examinations of the urine, that mercury is absorbed when used in this way, and from it he has obtained as good results as from any other method of treatment. He considers this plan a particularly safe one, salivation being avoided, while a very small amount of mercury is constantly passing into the circulation.—*London Medical Recorder*, September, 1890.

Aristol in Blepharitis and Keratitis.—In the *Revue Générale et de Clinique et de Thérapeutique*, September 18, 1890, the following directions are given for the use of his new remedy in the affections named above. The advantages claimed for aristol are its lack of odor and its efficaciousness. Employed in the following ointment, it has been found useful both in papular and ulcerative keratitis and in ulcerative blepharitis:

R.—Aristol	. . .	15 grains.
Vaseline } Lanolin }	of each . . .	75 " —M.

Apply a small portion of this daily to the surface which is affected. This ointment is not intended to displace the use of boric acid solutions, but may be employed in lieu of yellow precipitate.

Post-partum Hæmorrhage.—Küstner (*Deutsche medicinische Wochenschrift*) writes that hæmorrhage occurring immediately after delivery arises either from injuries or from the physiological utero-placental wound. Hæmorrhage from the laceration of the external genitals should be checked by compression or by sutures; hæmorrhage from laceration of the cervix should also be checked by sutures, drawing the uterus to the vulva by means of vulsellum forceps. To prevent atonic post-partum hæmorrhage, slow extraction of the child, besides waiting for the normal expulsion of the placenta, is recommended. Under no circumstances should attempts at placental expression be made during the physiological period of uterine relaxation (fifteen minutes), but we should wait until a number of spontaneous after-pains have occurred. To stop atonic hæmorrhage, Küstner recommends preparations of ergot, cornutin, heat, and bimanual irritation of the uterus. If these measures fail, he advises tamponing the uterus with iodoform gauze. The latter method he has used with satisfaction in eight cases, and believes that it is particularly useful when the

source of the hæmorrhage cannot at once be determined. In such cases the entire genital tract should be tamponed.

In the *Journal of the American Medical Association*, June 12, 1890, an editorial writer calls attention to the value of the faradic current in the treatment of post-partum hæmorrhage, and doubts the necessity of tamponing the uterus in cases of doubtful diagnosis.—*Archives of Gynecology*, October, 1890.

Epsom Salt in the Treatment of Acute Dysentery.—SURGEON A. W. D. LEAHY, of India (*Lancet*, October 4, 1890), has treated 103 cases of acute dysentery by the administration of a saturated solution of sulphate of magnesium, to which was added a small quantity of dilute sulphuric acid. In the early stages of dysentery this treatment, the author has found, is remarkably efficient; the temperature falls, mucus and blood disappear from the stools, which become copious, fæculent, and bilious; tenesmus ceases; the skin acts well, and the patient sleeps after the first few doses. The more chronic the case, the less apparent are the advantages of the treatment.

The method is carried out as follows: A drachm of the saturated solution of the salt with ten drops of dilute sulphuric acid are given every one or two hours, until the stools become more copious, fæculent, and free from blood and mucus, the temperature falls, and the pain and tenesmus cease. When the stools are normal in character and are reduced to two or three in the twenty-four hours, an ordinary astringent mixture with opium or cannabis indica is usually all that is necessary to complete the cure.

The advantages of this method over the usual ipecacuanha treatment are, that it has no depressing effect; that it produces neither nausea nor vomiting; and that it quiets and soothes the patient. It probably prevents the formation of ulcers by its influence upon the hyperæmia of the bowel.

Solution for the Eczema of Dentition.—

℞.—Hydrochlorate of cocaine 2 grains.
Bromide of potassium . 15 "
Pure glycerin } of each . ½ ounce.—M.
Distilled water }

Rub thoroughly together, and apply to the parts with the soft part of the finger. If insomnia is present, owing to the itching produced by the eruption, a teaspoonful of a syrup made up as follows will be found useful:

℞.—Bromide of potassium . 7 grains.
Syrup of orange . . . 1 ounce.—M.

For the cure of the condition, an ointment composed of oxide of zinc, 1 drachm, and vaseline, 3 drachms, may often be employed with advantage.

An Ointment for Carbuncle.—

℞.—Ichthyol . . . . 1 drachm.
Camphorated lard . . ½ ounce.—M.

This salve is to be applied three times a day around the inflamed area, and if the surface has become broken the tissues are to be touched with nitrate of silver. It is said that the ichthyol diminishes pain, favors the resolution of the swelling, and aids in cicatrization.

Subcutaneous Injections of Water.—PROFESSOR SAHLI (*British Medical Journal*, September 20, 1890) practises the subcutaneous injection of water containing 0.73 per cent. of sodium chloride in the following conditions:

1. In uræmia complicating the course of either acute or chronic nephritis. In such cases the injection of a quart of the solution once or twice daily is, as a rule, followed by rapid abatement of the symptoms, particularly if, in addition, digitalis is administered.

2. In the typhoid state, in which frequently after the first injection delirium ceases, the pulse becomes stronger and fuller, and the tongue more moist.

3. In Asiatic cholera, cholera nostras, and infantile diarrhœa.

4. In poisoning, particularly by substances that are eliminated by the kidneys.

5. When the use of fluid by the mouth is objectionable, as in cases of perforation of the stomach or bowels, peritonitis, etc.

6. In acute anæmia from hæmorrhage.

Sahli believes these injections "wash out" the system by inducing profuse diuresis and the elimination of solids with the urine: dilute the body-juices and the poisonous substances that may be contained therein; furnish water to dehydrated tissues, and raise lowered blood-pressure by filling the vessels.

The injections are given by means of a hollow needle the size of a knitting-needle, antiseptic precautions being carefully observed. One quart of the solution can be injected in from five to fifteen minutes, and the best situation is the subcutaneous tissue of the abdomen.

Mixture for Diphtheria.—KOUZNETZOW recommends the following as a local treatment in diphtheria:

℞.—Concentrated alcoholic solution of menthol } of each 1½ drachms.
Concentrated alcoholic solution of naphthalin }
Spirits of turpentine } of each 3 "
Glycerin }

This is to be painted over the surface which is involved.—*La Semaine Médicale.*

The Treatment of Hydrocele by Incision.—DR. SMIGRODSKI (*Bolnitchnaia Gazeta*, No. 12, 1890) reports fourteen cases of hydrocele treated by Volkmann's method. The ages of the patients varied between ten and sixty years. After incision the cavity of the tunica vaginalis was washed out with weak sublimate solution, the irrigation being continued during the dressing. In some cases the entire cavity was plugged with iodoform gauze, but, as a rule, small plugs of the gauze or fine drainage-tubes were inserted in the angles of the wound, the remainder of the incision being closed with both deep and superficial sutures. The plugs or drainage-tubes were removed in a few days, the sutures in from four to ten days. In the majority of cases primary union was secured, but where the walls of the sac were very thick the union was by granulation. As a rule, some swelling of the testicle on the side corresponding to the operation was observed. In one case a superficial abscess developed during convalescence, but all the cases were cured.—*Annals of Surgery*, October, 1890.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author.

THE ETIOLOGY OF TETANUS.

REFERRING again to the etiology of tetanus (see THE MEDICAL NEWS, October 18, 1890) the experiments of DR. E. O. SHAKESPEARE, of Philadelphia, are of considerable interest and importance. Although failing to discover tetanic microörganisms in the nervous system of tetanized animals, Dr. Shakespeare was able, by placing in contact with the central nervous system of healthy rabbits solutions of the spinal cords of tetanic cases, to produce in a short time the characteristic symptoms of the disease, while the subcutaneous injection of the same material proved absolutely innocuous. Further, the exclusion of the tetanogenous source by extirpating the infected sore or amputating the member in which it occurs, confirms the idea of a local activity with the manifestation of general influences from the elaboration of poisonous matters which circulate in the fluids.

Some observers are disposed to deny the infectious nature of tetanus, and consider the experimental form of the affection as not identical with the clinical variety. These differences between the experimental and clinical varieties are in the shorter period of incubation and more rapid course of the former, in the number of failures by inoculation, the lack of specificity of Nicoläier's bacillus, and in the failure of the ordinary antiseptic measures to check the course of the affection. However, the period of incubation in the experimental form is short, probably because of the relatively large amount of the virus inoculated. The point of manifestation is not constant in either the clinical or the experimental variety, the muscles of the back of the neck and of the jaw being usually first affected in the former, while in the latter the muscles of the part inoculated are perhaps more often the seat of the first symptoms. The shorter duration of the course of the experimental form is also to be expected because the virulence of the virus is so marked that fatal results are induced the more quickly. The failures to induce the disease by inoculation are explicable by the complexity of conditions of the proper growth of the microörganism in the animal economy. The positive refutation of the objection that Nicoläier's germ is not specific is, perhaps, at the present unattained; but the failure of the usual antiseptics in relation to the development of the affection simply bespeaks the great resistive power of the microbic cause to the action of the antiseptics. Nor should the fact of the occasional curative effect of operations upon nerves, as by cutting or excision, or stretching, lead to the conclusion that the fault exists in organic change of the nerve. The statement of its causation by violent emotional disturbances is to be regarded with considerable doubt, since, in the instances found in literature by MM. Verhoogen and Baert, the moral factor was invariably associated with injury and the opportunity for the ordinary traumatic form to occur.

Following the course of discussion thus outlined, MM. Verhoogen and Baert finally come to these conclusions:

"That tetanus is a disease of an infectious nature, presenting all the ordinary characters of a zymotic affection, both in its genesis and in its general course and symptoms.

"That the disease is also of a specific nature, arising from the action of a microbic cause constantly found in cases of tetanus, capable of inducing tetanus, and no other form of infection, upon introduction into the organism."

In connection with the above, the recent efforts of Peyraud to establish a tolerance for tetanus infection is a matter of interest. Recognizing the similarity between the action of strychnine and the alkaloids isolated by Brieger, this investigator has

attempted, by the introduction of strychnine into the economy by inoculation, to produce the effects of a vaccination, so to speak. Although the experiments as recorded would seem to be in general successful, the investigations leave much to be desired.

The local occurrence of the bacillus about the infected sore giving rise to general effects only secondarily, the question of the protective power of a previous attack of tetanus, and more especially the improbability of the identity of strychnine with the toxic principles evolved by the microörganisms in the animal economy, render extremely unlikely the existence of a protective influence by the vaccination of such vegetable alkaloid.

REVIEWS.

Dictionary of Practical Medicine. Edited by J. K. Fowler. Philadelphia: P. Blakiston, Son & Co., 1890.

This rather modest rival of Quain's larger book resembles it very closely indeed, not only in the general appearance of its pages, but also in the character of its articles. The names of the contributors are most of them so prominent that it is useless to attempt to mention any of them without mentioning all.

The editor has been fortunate in his selection of the authors, obtaining in nearly every case writers who are recognized as authorities on the subjects of which they treat. For those who do not care to purchase the much larger book of Quain, or who wish comparatively recent information concerning medical subjects in a somewhat narrow space, the book will certainly prove of value, and we heartily recommend it as one which will give a full return for the money invested in its purchase.

Familiar Forms of Nervous Disease. By M. Allen Starr, M.D., Ph.D. With illustrations, diagrams, and charts. New York: William Wood & Co., 1890.

In writing this comparatively small book Dr. Starr has certainly done the average member of the medical profession a favor, for the title of the work shows that it is the "familiar forms of nervous disease" which are described; not the rare disorders, seldom met with, but the forms seen by the ordinary practitioner in every-day life. Further than this, the book is so copiously illustrated by practical cases that the information it contains is directly applicable to the general practitioner's needs.

Dr. Starr's labors in this field have already placed him in the position of one of the leading neurologists of the country, and we can scarcely imagine that anyone can be found who would be better qualified to prepare such an aid to his medical brethren.

There are quite a large number of excellent prescriptions at the end of the book, and the illustrations are unusually clear in representing pictorially the statements in the text.

Ointments and Oleates, Especially in Diseases of the Skin. By J. V. Shoemaker, A.M., M.D. Philadelphia and London: F. A. Davis, 1890.

The labors of Dr. Shoemaker in the introduction of the preparations with which this book teems are so well known by those who are interested in skin diseases that it is only necessary for us to call the attention of our readers to the facts that the oleates have been received with very considerable professional favor on both sides of the Atlantic, and that the first edition of Dr. Shoemaker's book has been sufficiently popular to call for a second edition after the lapse of a few years.

To the physician who feels uncertain as to the best form in which to prescribe medicines by way of the skin the book will prove valuable owing to the many prescriptions and formulæ which dot its pages, while the copious index at the back materially aids in making the book a useful one.

The Pharmacology of the Newer Materia Medica, Embracing Botany, Chemistry, Pharmacy, and the Therapeutics of New Remedies. Detroit: George S. Davis, 1890.

This series of contributions to our knowledge of the action of some of the drugs which have been introduced into medicine during the past few years, is very valuable to every physician who desires to keep pace with the medical progress of the day; and we doubt not that Mr. Davis's venture in its publication will be well received by the profession. Although the parts will appear every month, and their issuance will extend over at least two years, the subscription price for the entire work is but $2.00.

We cordially recommend the series to our readers, and do not know of another investment which will bring so much information for so little money.

Manual of Hypodermic Medication. By Drs. Bourneville and Bricon. Edited by G. Archie Stockwell, M.D. Detroit: George S. Davis, 1890.

This is a little book with which, in other forms, some of our readers are doubtless well acquainted. It is certainly useful in giving the physician accurate information in regard to the branch of therapeutics of which it treats, but we cannot quite agree with some of the American editor's notes. Thus, he says, in a foot-note, that "the theory that injections made into one part of the body will be absorbed more rapidly than in another is absurd, since, as all injections obtain their effect by absorption into the circulation, it is evident the differences that may arise from locality are frequently inappreciable." Every one knows that in some portions of the body absorption occurs much more rapidly than elsewhere, by reason of a close network of lymphatics or bloodvessels; so that an injection into the forearm is certainly absorbed much more rapidly than is one which is sent into the broad of the back. Most of the additions made by Dr. Stockwell add considerably to the value of the book, and he has certainly increased its usefulness by adapting it to Americans, and made it more serviceable than the mere translation of the book would be capable of being.

SOCIETY PROCEEDINGS.

AMERICAN RHINOLOGICAL ASSOCIATION.

Eighth Annual Meeting,
held in Louisville, Kentucky, October 6, 7, and 8, 1890.

The Association convened at the Galt House and was called to order by the President, Dr. Arthur B. Hobbs, of Atlanta, Ga., at 3 P.M., who then delivered the

ANNUAL ADDRESS.

He said that the Association had met to exchange views, to profit by one another's experience and observations, and for the advantages of social intercourse.

Conservatism should not be too rigidly adhered to in the advancement of science, and in order that one may be a successful specialist in any branch it is necessary that he should have had some experience in general practice, and have studied all the branches of medicine.

Dr. Emmett Welsh, of Grand Rapids, Michigan, contributed a paper entitled

THE RELATION OF NASO-PHARYNGEAL DISEASE TO CATARRH OF THE MIDDLE EAR,

in which he said that the relationship existing between naso-pharyngeal disease and catarrh of the middle ear is intimate and inseparable. The ear depends upon a healthy condition of the nares and naso-pharynx for the healthy performance of its functions, and patients presenting themselves for the treatment of ear-disease always give a history of catarrh of the nose and throat. Therefore it is essential not only to become familiar with the speculum, the rhinoscopic mirror, the catheter, Politzer bag, etc., but also to detect the diseases of the nares and naso-pharynx, their inflammations and obstructive lesions, and to understand the treatment of such conditions.

A spur upon the septum may excite tinnitus aurium, when, of course, treatment of the ear alone would be useless.

Repeated attacks of subacute otitis are often directly referable to some mechanical obstruction or inflammatory condition of the naso-pharynx, but how often do we find that this is not detected and that treatment is directed to the ear only. This is best illustrated by children who suffer from recurrent attacks of otitis media; when the membrana tympani is found inflamed, the child breathes with difficulty and chiefly through the mouth, and an adenomatous growth is discovered in the vault of the pharynx.

Dr. T. H. Stucky, of Louisville, Kentucky, then read a paper on

TONSILLAR HYPERTROPHY, ITS INFLUENCE ON NASAL AND AURAL INFLAMMATION,

in which he said that of all the diseases of the upper air-passages, he knew of none more conducive to the production of serious after-effects than tonsillar hypertrophy.

As to the etiology, very little is found in current literature. The exanthemata, diphtheria, and frequent attacks of pharyngitis seem to be etiological factors. Sex is not without some influence in producing the affection, for out of 1000 cases recorded by Morell Mackenzie, 670 were males and 327 females. Some cases follow acute attacks of quinsy, hereditary or acquired syphilis, granular pharyngitis, etc. As a rule, after the age of thirty years spontaneous cure takes place, it being the natural tendency of the gland to atrophy after this age.

It is immaterial whether the hypertrophy be due to the engorgement of the crypts, to either an active or passive hyperæmia, or to a true inflammatory hyperplasia, the indications for treatment are important.

Where there is simple hypertrophy due to an acute catarrhal inflammation, applications of the mild astringents have proven in the author's experience of little benefit.

The rheumatic character of acute tonsillitis or hypertrophy is accepted by many, and salicylate of sodium at the commencement of the attack, in ten-grain doses every hour or two until one drachm has been taken, will abort many attacks. On account of the nausea frequently produced by this drug Dr. Stucky has used the effervescent salicylate of lithium with equally satisfactory results, and without causing nausea.

For simple acute hypertrophy the treatment should be constitutional; locally, astringents may be used. When the tonsils are soft the galvano-cautery is very effective, a few deep cauterizations being made twice a week. The author has introduced the galvanic needle its full length into the tonsils at several points about one-eighth of an inch apart, with excellent results. The galvano-cautery snare, if there is a history of hæmorrhagic diathesis, is a valuable addition to the armamentarium of the rhinologist, Morell Mackenzie recommends the use of "London paste," applied once or twice a week over various parts of the organ; but this method Dr. Stucky considers slow and painful. Where the organ is fibrous, dense, and hard, tonsillectomy should be resorted to. While the danger from hæmorrhage is reduced to a minimum, the time, suffering, delays, and inconveniences which are overcome by ablation render it, in his judgment, the operation for speedy relief, and should always be performed if the hypertrophy is dense. The gallo-tannic gargle of Morell Mackenzie is an excellent application to check the bleeding. The cold wire snare is painful and slow, and will eventually be superseded by the galvano-cautery. If the uvula and soft palate remain relaxed after tonsillectomy and the use of astringents, amputate the uvula. The ear-symptoms, if acute, generally subside rapidly. After removing the tonsils, special attention should be directed to the condition of the nasal passages. If long-standing hypertrophies exist, remove them by the cautery or other means.

Simple inflation of the Eustachian tube by the method of Politzer or Valsalva will often relieve the patient after a few repetitions, but these methods should never be used unless the nasal passages as well as the vault of the pharynx have been thoroughly cleansed. If there is no marked change in the tympanum the method of Delstauch—massage—will prove of service.

SECOND DAY.—MORNING SESSION.

Dr. E. R. Lewis, of Indianapolis, Indiana, read a paper entitled

NASAL CAUTERIES.

He has discarded every form of caustic paste in the treatment of nasal hypertrophies. In the treatment of pos-

terior hypertrophies, chromic acid can be easily and safely used by means of a guarded porte-caustique, and the practitioner who is not provided with the apparatus of a specialist and yet is called upon to treat nasal hypertrophies, will do well to use chromic acid in preference to any other caustic. Nitrate of silver is to be condemned in nasal treatment.

In Dr. Lewis's practice the galvano-cautery has taken the place of all other nasal cauteries. The galvano-cautery does its work neatly, aseptically, and, when properly used, painlessly and bloodlessly. For all nasal operations, except the removal of large growths by the loop, a small storage-battery is the most useful and convenient battery. The storage-battery in his office is kept constantly charged by four cells in the cellar beneath. It can be easily detached and taken out of the office and used for days without being re-charged. For the loop a larger or double battery is necessary, but even in that case the battery can easily be carried in the hand.

In the use of the galvano-cautery Dr. Lewis gave the following cautions:

1. Adopt preliminary treatment even if there is not much congestion or hyperæmia. The results are always more satisfactory after preliminary treatment of a few weeks, and the work to be done by the cautery can be better gauged.

2. Cauterize in the anterior portion and use the edge of the knife—not the flat surface—sinking it in as far as seems necessary and drawing it forward. It is best to keep the knife moving to prevent the tissues from sticking to it.

3. After the cauterization spray the parts thoroughly but gently with soothing solutions such as oil of vaseline, with a little eucalyptol in solution, followed by warmed Seiler's solution and finally oil of vaseline and eucalyptol. The oil may also be medicated with iodol.

4. Never cauterize both sides at one sitting.

5. Introduce the electrode while cold, apply it to the posterior part of the hypertrophy, then establish the circuit and draw the knife forward, the maximum heat having been determined by the rheostat. A bright-red heat gives the best results. Dr. Lewis never uses a black heat; a dull-red heat is apt to make the knife stick; a bright-red heat, even if inclining to white, seems the best. It must be remembered that the electrode is cooled by the secretions and tissues. The thumb should be removed from the button before withdrawing the electrode.

6. The parts should be treated gently for several days after cauterization, the secretions being removed with as little irritation as possible. If the other side is to be cauterized a week should be allowed to intervene, if possible, before doing it. The anterior part of the hypertrophy should be cauterized first, and the remaining portions at subsequent operations. Sometimes after a satisfactory cauterization of the anterior part, the posterior part can be easily removed with the snare, whereas it would have been very difficult to use the snare on the entire hypertrophy.

Apply cocaine by means of cotton on a probe, using a fresh ten-per-cent. solution. The cotton is gently applied to the anterior part of the swelling, held in position for a few seconds, then gently and slowly pushed back. Care is taken to have the sides and lower part of the hypertrophy well moistened by the solution, although the cotton must not be so saturated that the solution will run into the throat or drop on the floor of the meatus. In a few moments the parts are ready for the cautery. There is absolutely no pain; rarely is there a drop of blood; and after-pain is very unusual.

In a few cases slight nausea is felt at the close of the application of the cocaine, or during or after the use of the cautery. In such cases if a little wine or brandy is given the disagreeable feeling will pass off.

Dr. J. G. Carpenter, of Stanford, Ky., followed with a paper on the

NASAL AND PHARYNGEAL MANIFESTATIONS OF SYPHILIS,

in which he said that primary syphilis, including the development of the chancre and infection of the adjacent glands, is infrequent in the nasal and pharyngeal chambers, though more frequent in the mouth and upon the lips; consequently it is the secondary form of syphilis and its sequelæ which chiefly concern the rhinologist.

The presence of the initial lesions of syphilis in the nasal or pharyngeal chambers causes swelling of the mucous membrane, pain, fever, infection of adjacent glands, and, in the nasal chambers, difficult nasal respiration.

Syphilitic rhinitis may result from heredity; the local lesions of secondary syphilis found in the upper air-passages may begin as a catarrhal inflammation, a rhinitis or pharyngitis, a local circumscribed erythema, or as a papular, pustular, or tubercular deposit. The epithelium of the mucous membrane rapidly becomes softened, disintegrated, and abraded, leaving one or several erosions that are quite painful and sensitive, and at first are bathed in a mucous secretion, which soon becomes muco-purulent or purulent as the ulcers enlarge and disintegrate.

In the treatment of syphilis of the nose and throat it is very important to arrest the disease as early as possible in order to prevent destruction of tissue and consequent deformity of the nose, palate, pharynx, and larynx. The anterior or posterior nares or Eustachian orifices may be occluded by adhesions.

The continuous use of mercury for from one to three years in small tonic doses, insufficient to produce tenderness of the gums, ptyalism, or relaxation of the bowels, is the most appropriate treatment for the permanent cure and eradication of the disease. The protiodide, the bichloride, and the biniodide of mercury stand at the head of mercurial preparations. External applications to the groins, axillæ, and thighs are adjuvants of the greatest importance in the treatment of syphilis.

The local treatment of syphilitic lesions of the naso-pharynx and larynx should consist in mild antiseptics and soothing applications to disinfect, soften, and wash away the morbid secretions and crusts.

For the treatment of the sequelæ of syphilis, such as caries, and necrosis of the bone and cartilage of the naso-pharynx and larynx, the same surgical rules hold good as in other localities, viz., to remove the dead bone, prevent further disintegration, and render the wound aseptic.

Afternoon Session.

Dr. John North, of Toledo, Ohio, contributed a paper on

NASAL HYPERTROPHIES,

in which he said that the term nasal hypertrophy is frequently applied to every condition of the nasal mucous membrane in which there is thickening of the membrane and narrowing of the lumen of the nasal cavities, not dependent upon anatomical abnormalities or tumors.

Dr. North divided hypertrophies into (1) chronic hyperæmia, (2) simple hypertrophy, (3) hypertrophy with hyperplasia, (4) hyperplasia, and (5) neoplasms.

In hyperæmia we have a superabundant supply of blood to the parts, dependent upon some derangement —paresis—of the vasomotor nervous system.

Simple hypertrophy is due to hyper-nutrition. There is no increase in the relative number of tissue-elements, but simply overgrowth of existing elements, dependent upon increased supply of nutrient pabulum.

Hypertrophy with hyperplasia may be due to hyper-nutrition from hyperæmia or congestion and inflammation produced by various causes.

Hyperplasia is caused by hyper-nutrition, congestion, and inflammation. In nasal hyperplasia there is no overgrowth of the tissue-elements. The increase in the thickness of the membrane is due to the organization of the products of inflammation thrown out from the vessels in the stage of congestion and exudation. Atrophy usually follows hyperplasia of the nasal mucous membrane.

Neoplasms usually appear upon the posterior part of the turbinated processes; the surfaces are rough and irregular.

In the treatment of true hypertrophy all that can be done by sprays of medicated vaseline is to cleanse the membrane and protect it from further irritation, permitting nature to cure the case. Prompt and permanent relief can be obtained by the removal of a small portion of the excessive growth. In these cases Dr. North prefers chromic acid, because it can be applied to a small portion of the membrane; and because it is circumscribed in its action, and the cicatricial tissue that it produces continues to shrink for a considerable time. He finds the membrane in a better condition several months after the operation than it was at first. A spray of medicated vaseline should be used during the entire treatment.

In cases of hyperplasia the local application of iodine in vaseline is of the greatest importance. Neoplastic growths are easily removed by the snare, chromic acid, or electro-cautery. Constitutional treatment should never be neglected in any case.

Dr. Carl H. von Klein, of Dayton, Ohio, read a paper entitled

ADMINISTRATION OF MORPHINE BY THE NOSTRILS.

Dr. von Klein has administered morphine through the mucous membrane of the nose in more than one hundred cases with very satisfactory results. It is simply snuffed into the nasal chambers, and the dose is divided into two equal parts. He has found that this mode of administering morphine is the most satisfactory, and that the drug is more prompt in its action than when administered either by the mouth or hypodermically.

Dr. A. B. Thrasher, of Cincinnati, Ohio, in a paper on

NASAL REFLEXES,

said that the multiplicity of symptoms attributed by modern rhinologists to nasal reflexes has caused not a little opprobrium to fall upon the specialist.

Among the affections attributed to intra-nasal lesions are: Asthma, hay-fever, cough, spasm of the glottis, gastralgia, dyspepsia, tumefaction and redness of the skin of the nose, œdema of the conjunctiva, conjunctivitis, photophobia, epiphora, asthenopia, glaucoma, scotoma, salivation, cardiac palpitation, disorders of smell, taste, hearing, and sight, huskiness of the voice and aphonia, exophthalmic goitre, rheumatic pains, vertigo, chorea, epilepsy, melancholia, agoraphobia, aprosexia, neurasthenia, migraine, cephalalgia, neuralgia, nocturnal enuresis, many uterine disorders, affections of the genito-urinary mucous membrane, etc.

Many of these affections are not true reflexes, but are caused by changes in blood-pressure, or by extension of inflammation by continuity of tissue. The specialist should carefully examine the nose, but he should also be a general physician and search the entire system for the often obscure *causus morbi*.

Dr. Thrasher reported two cases of salivation due to intra-nasal disease. He thought that in these cases the cause of the nasal reflex was twofold. Primarily, a diseased condition of the respiratory tract of the nose. Secondarily, an abnormal irritability of the central nerve-ganglia. This affection of the central nervous system may have been caused by repeated irritation of the intra-nasal tissues, or by some extra-nasal irritation.

In reflex diseases arising in the nose, vasomotor paresis, very different from active inflammation, is generally present, although it may be masked by acute inflammation.

The immediate exciting cause of the reflex may be a mechanical, chemical, or thermal irritant.

There is at times some difficulty in making the diagnosis, as the severity of the reflex is not in proportion to the amount of nasal disease. Sometimes the local application of cocaine will abolish the reflex; or again, it may be excited by the irritation of a nasal probe: but these means are not always to be relied upon.

As a rule, constitutional as well as local treatment must be instituted.

It is apparent that in these reflex disturbances the specialist should be broad in his ideas, not viewing the whole world through his nasal speculum, and not expecting to see all bodily ailments reflected in his rhinoscope.

Third Day.—Morning Session.

Dr. R. S. Knode, of Omaha, Nebraska, contributed a paper entitled

WHAT SHALL BE OUR EXCIPIENTS IN NASAL SPRAYS?

which elicited a spirited discussion.

The subject of

HAY-ASTHMA

also came up for general discussion, which was opened by Dr. A. de Vilbiss, of Toledo, Ohio.

OFFICERS FOR 1891.

President.—Dr. R. S. Knode, Omaha, Neb.

First Vice-President.—Dr. T. H. Stucky, Louisville, Ky.

Second Vice-President.—Dr. C. F. McGahan, Chattanooga, Tenn.

Secretary and Treasurer.—Dr. E. R. Lewis, Indianapolis, Ind.

Place of next meeting, Indianapolis, Indiana.

CORRESPONDENCE.

LONDON.

The Opening of the Medical Session—Dr. Broadbent's Address at Leeds—Dr. Barlow's Introductory Address—The late Dr. Matthews Duncan.

To the Editor of The Medical News.

Sir: The first of October has come and gone and brought with it the usual crop of introductory addresses of varying degrees of merit. In London, King's College, owing to building operations, was obliged to forego its "introductory." The provincial schools have of recent years fallen into the habit of summoning eminent men to deliver the time-honored oration, and this year Sir James Paget held forth at Liverpool, Sir Spencer Wells at Manchester, and Dr. Broadbent at Leeds. It is a matter of some difficulty nowadays for the lecturer to know whom he is supposed to be addressing, the new students, the old ones, or those who have already entered upon the active duties of their profession.

Sir Spencer Wells assumed that the latter formed the bulk of his audience, and delivered a weighty address on national sanitation, which of course gave him an opportunity to say a good word for cremation, of which he is one of the chief champions in England. Dr. Broadbent, on the other hand, addressed himself to the new students, and gave them much excellent advice. He began by expressing his dislike of the increase in the length of the curriculum, and thought that the old and shorter course had turned out excellent practitioners. Speaking of lectures, he said: "It is the fashion to decry lectures, but I will venture to say that there are very few courses of lectures which do not teach more than is found in books, and very few men who will not find something to learn from lectures after most careful reading. The subject is a living one in the lecturer's mind, and it will be set forth with greater emphasis of the important points than is possible in print; but if you really want to profit by a lecture you must have read up the subject so that it is familiar to your minds." Speaking of the importance of clinical work in the wards and of the familiarity with the physiognomy of disease thus to be obtained, he said: "Knowledge of this kind cannot be conveyed in books or imparted by a teacher. It is by the eye that you have to be guided when a case first comes before you, and you can see how important it is to have at once a clue to the nature of the malady. Books and lecturers can, it is true, tell you what to look for, but you must look for yourselves, and from the moment you enter the hospital you should make it an object to fix in your minds the indications of disease apparent in the face. You should say to yourselves when you first see a case, 'Now, what is the matter with this man?' and every time you see him later you should ask yourselves, 'Does he look better or worse?' When you are in practice you will have to answer this question every day both to yourself and to the friends of the patient, and the confidence you inspire (and, indeed, your own usefulness) will greatly depend on the promptitude and justice of your answers. Perhaps the most valuable feature of the old apprenticeship system, now dead and buried, was, that observation of a patient's appearance and attention to what he said about himself were enforced."

Two other pieces of advice he gave to those about to become clinical clerks which they will certainly do well to bear in mind; one was that they should keep notes of all the cases under their own care, either a copy of the ward notes or an abstract of them, and the other was that they should read up in the text-books the disease illustrated by each case. There is no doubt that the chief cause of failure in students of the present day is their unwillingness to learn to think for themselves; they want to be taught everything, and seem to believe that when they have taken the history and "present state" of the patient allotted to them they have done their share, and that the physician in charge of the case ought to do the rest.

Against this idea and the modern system of preparing for examinations Dr. Barlow raised his voice in his introductory address at University College, for whereas formerly, he said, it was only the stupid and the lazy who were crammed, now many feel themselves obliged to resort to cramming in order to get through their examination. Amongst the reasons for this change he thought perhaps that the teaching was not sufficiently catechetical, and he admitted that the standard of the examinations has been considerably raised; but what he chiefly objected to was the modern system of allowing a man to pass his examination piecemeal. He felt very strongly that if a man was not able to pass in all the branches of his subject at the same time he ought to be rejected, and if it could be shown that the standard of the examinations was too high, this should be lowered. Like Dr. Broadbent, he disapproved of the old system ot apprenticeship, and warned his hearers that medical education was yearly becoming more exacting, and the strife for competency and even livelihood more severe.

During the summer vacation the death of Dr. Matthews Duncan has deprived St. Bartholomew's Hospital, and, indeed, all London, of one of the foremost clinical teachers. He possessed in a high degree that essential quality of dogmatism, without which none can become a successful teacher. In private life he was, I believe, most genial, but in his work the uncompromising way in which he formed and adhered to his opinions often led people to think him harsh. The best bit of luck that ever happened to him was when, some fourteen years ago, he was passed over for the professorship of his own specialty in Edinburgh, for this left him free to accept the invitation which he received almost directly afterward to join the staff of St. Bartholomew's Hospital. This in itself was more than compensation for the disappointment he had just experienced, and he also at

once stepped into the front rank of London consultants. He was for some years on the General Medical Council, but the qualities which stood him in such good stead in the lecture theatre and at the bedside were not so well appreciated there, and he must have felt that he had not the weight which his position in the profession might reasonably have entitled him to expect. His term of office at the hospital had nearly expired, and curiously enough amongst his papers was found a letter tendering his resignation and dated December, 1890. Speculation is rife as to who will be fortunate enough to be his successor, for the post of physician, accoucheur, and lecturer at St. Bartholomew's Hospital is one that anybody might be proud of.

LOUISVILLE.

To the Editor of The Medical News,

Sir: The meetings of the American Rhinological and the Mississippi Valley Medical Associations, recently held in Louisville, were successful, both from a scientific as well as from a social standpoint.

Many able papers were read and on the evening of October 9th, Liederkranz Hall was filled to its utmost capacity with the laity and medical students, who came to hear Dr. John A. Wyeth's address on "The Medical Student." The address was an excellent one and was interspersed with numerous incidents of the author's career as a physician and surgeon. He read from manuscript, and used but few gestures, standing with his right hand in his trousers pocket, and holding his manuscript in his left hand. Dr. Wyeth is a very entertaining speaker, and his address was frequently interrupted by applause of the heartiest nature.

He said that he had passed through the varying experiences of a checkered career. He had, in accordance with the suggestion of the Litany, done those things which he should not have done, and had left undone those things which he should have done. He had been in many places where he had no business to be, but never in his life had he found himself in a position where he had so little business to be as in Louisville, trying to deliver an address to the best brains of the profession in the Mississippi Valley.

He further said that were he to launch forth with some pet problem in surgery, the obstetrician would find it convenient either to "talk shop" to anyone who would sit still for a minute under the infliction, or else walk out to the nearest instrument-maker and order a pair of forceps after his own model. The ophthalmologist would close his eyes and swear that the reader of the paper had a mental strabismus not amenable to any treatment except amputation of the head at the occipito-atloid articulation. The aurist would grow deaf to his enthusiasm, and the neurologists present might possibly forget themselves and speak to each other—an accident which has not so far occurred in the records of the New York profession. The practitioner in general medicine would surely grow weary, and all of the listeners might go to sleep, except the gynecologists—who never sleep. They might not find anything of special value in his theme, but the live gynecologist is not for a moment going to take his "weather eye" from the others of his group.

A few words relative to Dr. Wyeth's rather remarkable career may not be amiss. He came to Louisville about thirty years ago. He was eventually graduated, returned to his home and hung out his shingle. But somehow or other the people became very healthy, or else took their ills to some one else. The occasional "nigger" or two, with a "misery" in his chest or shaking with ague, would drop in on the new doctor, but that was all. Paying patients ignored his very existence.

He stood it for a time, and then, it is said, took to steamboating, a calling in which youth is no barrier to success. He followed a river-life for several years, just how many we are not able to ascertain, when the old "fever" returned and he wanted to be a doctor again. At that time he heard of the feats of surgery performed in New York, and thither he directed his steps. Again he matriculated, and again was graduated, this time with a view to follow surgery exclusively. Unlike his experience in Mississippi, he did not lack for patients in New York. Difficult cases of surgery in hospital and private practice became the rule instead of the exception with him. His fame began to spread, first in New York, then from city to city, until it became national—may we not say international? In the meantime he married the daughter of the famous Marion Sims, which also contributed to bring him into prominence. On Wednesday, October 9th, he returned to Louisville, the first time since he was graduated from the gloomy old building at Eighth and Chestnut Streets, thirty odd years ago. He left here a raw recruit in the ranks of the medical professsion; he returned as one of the most distinguished surgeons in the country.

Immediately after the conclusion of Dr. Wyeth's address, the visiting and local physicians attended a reception given in honor of the Association by Drs. D. W. Yandell and W. O. Roberts. Dr. Yandell's house was brilliantly illuminated for the occasion. The reception hours were from nine to twelve o'clock, and during this time there was an almost constant stream of visitors going and coming. The occasion was an enjoyable one, and every guest was pleased with the hospitable treatment received.

Dr. W. H. Wathen gave a formal dinner at his residence, in honor of Dr. Wyeth, at which the following gentlemen were present: Drs. W. P. King, of Kansas City; R. Stansbury Sutton, of Pittsburg; William Porter, of St. Louis; John H. Rauch, of Chicago; John H. Hollister, of Chicago; Frank Woodbury, of Philadelphia; George Hulbert, of St. Louis; and E. S. McKee, of Cincinnati.

Dr. Wyeth demonstrated at the University of Louisville his operation of bloodless amputation at the hip-joint on a cadaver, after which Dr. J. W. Heddins performed Macewen's operation for the radical cure of hernia.

Dr. T. H. Stucky, of Louisville, banqueted the members of the American Rhinological Association.

The banquet tendered to the visiting physicians of the Mississippi Valley Medical Association was a very elaborate one. The tables were handsomely decorated for the occasion, and more than two hundred guests were present.

Dr. D. W. Yandell acted as toastmaster. In front of

his chair was a large bank of colored chrysanthemums, from which extended, on either side, through the centre of all the tables, a pathway of vines and flowers. Around the room each window was filled with potted plants and shrubs, while the tables themselves, with baskets of fruits, presented a most inviting appearance.

The first page of the *menu* was ornamented with a skull and cross-bones, flanked on either side by a hypodermic syringe and a scalpel.

While on such occasions men are liable to become "inebriated with the exuberance of their own verbosity," yet the responses to the various toasts at this banquet were very humorous and instructive. If outsiders had heard the speeches, we feel confident they would say that doctors, as a whole, are as good after-dinner speakers as are members of the bar or any other profession.

A word of praise, in conclusion, is due Dr. I. N. Bloom, Chairman of the Committee of Arrangements, for the clever and excellent manner in which he handled and placed the many guests, and looked after their comfort generally. It was not a small task by any means, but it was most gracefully and creditably performed.

MONTREAL.

To the Editor of The Medical News,

Sir: The importance of Montreal as a medical centre is indicated by the statement that it has a population of 240,000, contains four medical schools, three veterinary schools, and a school of pharmacy, three general hospitals, a women's hospital, and numerous homes and dispensaries available for medical teaching. The two lunatic asylums on the island do not as yet furnish regular clinical instruction.

The terrible catastrophe by fire at the St. Jean de Dieu Asylum is doubtless still fresh in the minds of the readers of The Medical News. The buildings have been rebuilt, and are again occupied, the management remaining in the hands of that wonderful woman, Sister Thérèse. The contract system, still in vogue, is held by many of the medical profession to be unsatisfactory. The Protestant Hospital for the Insane has recently been opened. It is on a fine site on the banks of the river, about three miles southwest of the city proper. The splendid new Victoria Hospital, at the base of the mountain, the munificent gift of two of our citizens, is progressing favorably, and it is expected will be completed within a year.

The medical schools opened on the first of October. The fifty-eighth session of the Medical Faculty of McGill University was opened by Dean Craik. His address was largely a retrospect of medical teaching in general, and at McGill in particular. In the teaching staff the principal changes are the retirement of the veteran surgeon, Fenwick, who is succeeded by Dr. T. G. Roddick, and the addition of Dr. James Bell to the chair of clinical surgery, as lecturer. Dr. Fenwick retires to the well-earned *otium cum dignitate* of the Emeriti staff after thirty years of active work in connection with the university. Two hundred and sixty-five students are already in attendance, of whom seventy are freshmen. The veterinary school, under Dr. McEachran, has been affiliated, and is now designated the Department of Comparative Medicine. The twentieth session of the Medical Faculty of Bishop's College was opened without any formal address. Thirty students were enrolled. This faculty has just made arrangements for the admission of women, the only medical school in the Province which has done so, and several female students have taken advantage of the opportunity. Separate dissection-rooms and cloak-rooms are provided, but in most of the branches co-education goes on. At Victoria and Laval the instruction is in French, and at the first of these one hundred and eighty students are in attendance, while Laval has seventy-five. All attempts at amalgamation of these two schools have so far failed. Both are more or less thoroughly under Roman Catholic clerical domination, and the nursing in the Hotel Dieu and Nôtre Dame, the hospitals in which their clinical teaching is done, is by the nuns.

The Victoria school presents the curious anomaly of an essentially French and Catholic faculty affiliated with a Methodist university, viz., the Victoria of Coburg. The College of Pharmacy has opened its twenty-third session in a new and commodious building on Palace Street. The lectures here are duplicated in French and English. Both professors of materia medica are medical men. Sixty-five students attend.

Our medical societies also resumed their work with the beginning of October. At the last meeting of the Medico-Chirurgical Society Dr. Roddick showed a remarkable case of fragilitas ossium. The patient, a healthy and well-formed lad as to trunk, upper extremities, and head, of thirteen years, had already suffered *twenty-eight* fractures of the lower extremities: nine of the left thigh, fifteen of the right, and two of each leg. The first occurred at the age of eighteen months. The boy was one of several children, the rest of whom showed no abnormality. The family history also was good. The little fellow did not suffer much pain, and had become so accustomed to the accidents that latterly he had applied his splints himself without medical aid. The limbs were much distorted and worse than useless, the right femur being ununited. He drags himself around on the buttocks by means of his hands. Dr. Roddick has decided to amputate.

Among the pathological specimens presented the same evening, was one showing bacillary tubercle on the cardiac valves, from a case of general tuberculosis in an infant. Dr. Johnston, the pathologist, stated that this condition was very rare.

Dr. T. E. D. d'Orsennens, the *doyen* of the Montreal School of Medicine and Surgery, and of the profession of the city, is to be banqueted at the St. Lawrence Hall on the evening of the 16th inst., on the occasion of his jubilee of medical practice. It will be an interesting event, as the fatherly Professor of Obstetrics is held in great esteem, alike by his French and English *confrères*.

BOSTON.

To the Editor of The Medical News,

Sir: Since the last letter from Boston a few changes that may be of interest to your readers have occurred. The City Hospital has now grown to large dimensions, having had 6715 in-patients and 13,605 out-patients during the year 1889. This growth has necessitated the building of a new surgical wing and a department for

infectious diseases, and the addition of three surgeons to the staff. Presumably the three out-patient surgeons will be appointed to the house-staff. The only changes as yet announced, however, are that Dr. Burrell has gone into the house, and that Dr. Munks has been appointed to the out-patient service. The contagious-disease department is an isolated building with its own set of servants, nurses, house pupils, and physicians. The latter are drawn in turn from the general staff for short periods of service, during which time they do no other work in the hospital. Excellent rules to guard against the danger of those on service carrying contagion have been adopted.

Several changes have also been made in the dispensary staff. A large number of patients are treated in the dispensary, but its great value in the education of the younger physicians does not seem to be appreciated. During last year there were 24,456 out-patients and 15,122 district patients treated. Curiously enough, the medical school makes but little use of this large amount of material for teaching purposes, presumably because the staff are supposed to be young men. In reality few are under thirty, and the average age is about forty years.

The triennial catalogue of the Massachusetts Medical Society shows a total of 1587 active members, of whom only about thirty-four are women. One-half of the women practise in Boston, while the city directory gives about 140 women in the list of physicians. No conclusion as to the quality as a whole of the women doctors can be drawn from these figures, since many of the most prominent have not joined the State Society.

The Medical Library is still in its old building, and probably will be for some time to come. A report just issued gives $29,263 as the assets of the library, $5371 as the income, and $4711 as the expenditure.

The Medical Department of Harvard University appears to be in a flourishing condition, the new students considerably outnumbering those of former years. The new laboratory, now approaching completion, is three stories high and sixty feet long, extending to the east of the main building. The basement is given up to store and animal rooms, the latter being large, light, and well ventilated. The ground floor is devoted to the bacteriological department; it has a large general workroom and special rooms and closets for coats, glassware, thermostats, sterilizing apparatus, library, chemical work, etc., besides a room for the instructor and four smaller ones for special workers. The old quarters in the main building are to be retained for undergraduates. The two upper stories are divided into rooms for the pathological department and photography.

THE MEDICAL SOCIETY OF VIRGINIA.

To the Editor of The Medical News,

Sir: With your kind permission I would like to correct a few errors in the reported abstract of my remarks before the Medical Society of Virginia, and which are found on page 349 of The Medical News. I am reported as saying that puerperal malarial fever is a common complication or sequel of labor, and that it is often followed by rheumatism.

The tenor of my remarks was that malarial fever did complicate the puerperal state in certain cases, but I did not mean to say that it did so frequently. In an illustrative case of puerperal malarial fever which I narrated, I mentioned that *acute articular rheumatism* followed that fever, and I further stated that I had occasionally seen acute rheumatism as a complication of the puerperal state. In regard to the removal of the uterine appendages, I insisted that they should be ablated only when restoration to health could be accomplished in all probability by no other procedure. My remarks in reference to ectopic gestation were also misapprehended, possibly by my want of lucidity. I did not say that Mr. Tait had confounded *hæmatocele* and *hæmatoma* with extra-uterine pregnancy. I stated that Mr. Tait in discussing the relations of tubal pregnancy to hæmatocele did not distinguish between a free effusion of blood into the peritoneal cavity and retro-uterine hæmatocele in the true signification of the term, and consequenttly introduced elements of confusion; and further, that an escape of blood into the connective tissue of the broad ligaments should not be called *extra-peritoneal hæmatocele*, but *hæmatoma*.

Very respectfully,

George Tucker Harrison, M.D.

NEWS ITEMS.

Diphtheria in Connecticut.—At Taftville, Conn., a village of French-Canadians, who work in the cotton-mills in or near that town, diphtheria has been allowed to spread by very imperfect sanitation. The disease was not known to exist in the place in the early summer, but appeared about three months ago, and it is reported that not less than fifty cases, with many deaths, have occurred. The habits of the villagers are secretive and opposed to ordinary sanitary regulations. Moreover, they dwell in large tenements, and are very much crowded. The same vehicles that are used at funerals are used for social purposes, and are not disinfected. Very few infected articles have been destroyed. One man, who lost four of his children by the disease, was in the habit of peddling milk from house to house during the time that his children were ill with the disease. In one house the health officer found the bodies of three small children, victims of diphtheria, upon a single bed. In another house, a child was sick with the disease, while five other children of the family were attending the village school. In adjacent villages a few cases of diphtheria have been observed, and were traced to the epidemic in Taftville.

The Loofah Bandage-material.—A writer in the *Chemist and Druggist* says that possibly the most important application of the "loofah," or towel-gourd of Egypt, will be in the manufacture of surgical bandage-stuffs. Bandages made of this material are already offered for use. In Germany soles for slippers are made from the loofah, and it is claimed that these soles are extremely elastic and are washable; they are constantly dry, and will keep the feet cool in summer and warm in winter. The loofah also makes an admirable undercloth for the saddle, as it rapidly absorbs moisture.

Mississippi Valley Medical Association.—The meeting of the Mississippi Valley Medical Association at Louisville,

on October 8th, 9th, and 10th, was the most numerously attended and successful of the sixteen meetings of the Association. There were more than eighty papers on the programme, which was completed on the third day by a rigid observance of the limit-rule in reading papers and in discussion. The only thing which marred the occasion was the illness of the President, Dr. Joseph M. Matthews, of Louisville. He received a wound several weeks ago which resulted in blood-poisoning, and, although his condition was much improved, he was able to preside at but few of the sessions. He worked hard during the summer for the success of the meeting, and was keenly disappointed that he was prevented to a great extent from participation in its scientific and social pleasures. An entertainment at the Blind Asylum, for the visiting ladies, was highly appreciated by those so fortunate as to attend. The ladies' reception at the Galt House brought forth the beauty and chivalry of the Falls City in hosts, and more than one bachelor doctor left his heart or a part of it behind him. This was followed by a banquet to two hundred and forty guests at the Galt House, from which the last stragglers found their way some time before daylight in the morning.

The Southern Surgical and Gynecological Association.—This Association will hold its annual meeting at Atlanta, Ga., on November 11, 12, and 13, 1890, under the presidency of Dr. George J. Engelmann, of St. Louis. From the preliminary programme which has been issued, as well as the standing of the Association, there will undoubtedly be an unusually interesting meeting held, and members of the profession who can manage to be present, and who are interested in these branches of medicine, will be amply repaid for the trouble of going to Atlanta.

Obituary.—Dr. Montrose A. Pallen, of New York, died October 1st, aged fifty-four years. He was a native of Vicksburg, Miss., and was educated for the priesthood in the Catholic Church. He preferred medicine, however, and was graduated in 1856 by the medical department of the St. Louis University. During the late war he was medical director in the Confederate army, under General Hardee, and filled other important medical positions. About sixteen years ago he removed from St. Louis to New York to take the chair of gynecology in the University Medical School. For the past four years Dr. Pallen was compelled to abandon the more active parts of his professional pursuits, on account of frequently recurring attacks of angina pectoris, but acted as resident physician to the Albemarle Hotel, where he lived a retired life, and where his death occurred. Dr. Pallen had travelled extensively, and was a highly cultivated and an exceptionally generous man.

—— Dr. Peter Hood, a highly-honored London practitioner, died recently in his eighty-second year. He is said to have been one of the reformers who stayed the hand of phlebotomy, especially in diseases of children, early in the present century. His writings were much sought after at one time, his book on gout and rheumatism having passed through three editions. He advocated the treatment of cancer by means of testa preparata, or oyster-shell, for the purpose of superinducing a premature calcification of the nutrient and involved arteries of the invaded tissues, a method of treatment that was practised to a limited extent in this country.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY FOR THE TWO WEEKS ENDING OCTOBER 18, 1890.

Braisted, William C., Detroit, Michigan.—Appointed an Assistant Surgeon in the U. S. Navy.

Wales, P. S., *Medical Director.*—Detached from temporary duty as a member of the Medical Examining Board.

Ames, H. E., *Passed Assistant Surgeon.*—Detached from temporary duty as a member of the Medical Examining Board.

Herndon, C. G., *Surgeon.*—Ordered to Naval Hospital, New York.

Persons, R. C., *Surgeon.*—Detached from Naval Hospital, New York, and await orders.

Scott, H. B., *Passed Assistant Surgeon.*—Ordered before the Retiring Board.

Price, A. F., *Surgeon.*—Detached from Naval Dispensary, Washington, D. C.

Anderson, Frank, *Passed Assistant Surgeon.*—Ordered to Naval Dispensary, Washington, D. C.

White, C. H., *Medical Inspector.*—Ordered to hold himself in readiness for duty on the U. S. S. "San Francisco."

Braisted, William C., *Assistant Surgeon.*—Ordered to the Army and Naval Hospital, Hot Springs, Ark.

Spratling, L. W., *Assistant Surgeon.*—Ordered to hold himself in readiness for orders to the U. S. S. "San Francisco."

Siegfried, C. A., *Surgeon.*—Ordered to the U. S Trainingship "New Hampshire."

Blackwood, N. P., *Assistant Surgeon.*—Detached from duty in the Bureau of Medicine and Surgery, and granted leave of absence.

Stone, L. H., *Assistant Surgeon.*—Detached from the U. S. S. "New Hampshire," and wait orders.

Edgar, John M., *Passed Assistant Surgeon.*—Ordered to hold himself in readiness for duty on the U. S. S. "San Francisco."

Gardner, J. E., *Passed Assistant Surgeon.*—Detached from the "Albatross," and wait orders.

Bright, George A., *Surgeon.*—Detached from temporary duty at the Naval Academy, and placed on waiting orders.

Ayres, J. G., *Surgeon.*—Detached from temporary duty at the Naval Academy, and placed on waiting orders

Lumsden, George P., *Passed Assistant Surgeon.*—Detached from the U. S. S. "Boston," and granted three months' leave.

Auzal, E. W., *Passed Assistant Surgeon.*—Detached from the Naval Academy, and ordered to the U. S. S. "Boston."

Smith, Howard, *Surgeon.*—Ordered to appear before the Retiring Board at Mare Island, Cal.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FROM SEPTEMBER 8 TO OCTOBER 4, 1890.

Hutton, W. H. H., *Surgeon.*—Detailed as Chairman of Board of Examiners, October 2, 1890.

Long, W. H., *Surgeon.*—Detailed as a member of Board of Examiners, October 2, 1890.

Purviance, George, *Surgeon.*—Granted leave of absence for thirty days, September 10, 1890.

Godfrey, John, *Surgeon.*—Detailed as Recorder of Board of Examiners, October 2, 1890.

Wheeler, W. A., *Passed Assistant Surgeon.*—To proceed to New Orleans, La., for temporary duty, October 3, 1890.

Banks, C. E., *Passed Assistant Surgeon.*—Granted leave of absence for twenty days, October 3, 1890.

Ames, R. P. M., *Passed Assistant Surgeon.*—To proceed to New Orleans, La., for duty, September 13, 1890.

Pettus, W. J., *Passed Assistant Surgeon.*—To proceed to Vineyard Haven, Mass., for temporary duty, October 1, 1890.

Hussey, S. H., *Assistant Surgeon.*—To proceed to New Orleans, La., for temporary duty, September 19, 1890. To proceed to Norfolk, Va., for temporary duty, October 3, 1890.

Wertenbaker, C. P., *Assistant Surgeon.*—Granted leave of absence for twenty days, September 12, 1890.

Perry, J. C., *Assistant Surgeon.*—Upon expiration of leave, to rejoin station at Mobile, Ala., September 29, 1890.

Young, G. B., *Assistant Surgeon.*—To proceed to Memphis, Tenn., for temporary duty, September 13, 1890. To rejoin station, St. Louis, Mo., when relieved at Memphis, Tenn., October 3, 1890.

ORIGINAL LECTURES.

MACEWEN'S OPERATION FOR HERNIA—EXCISION OF A BUBO—WHITEHEAD'S OPERATION FOR HÆMORRHOIDS.

A Clinical Lecture,
delivered at St. Luke's Hospital, New York.

BY B. FARQUHAR CURTIS, M.D.,
ATTENDING SURGEON.

GENTLEMEN: This patient, who is a single man, forty-three years of age, first noticed a tumor in the left groin about twelve years ago, after a severe muscular effort. It grew to the size of a hen's egg, and then remained stationary for five years, when another muscular strain was immediately followed by the appearance of a similar tumor in the right groin. These tumors increased until they formed a mass about the size of a man's head. These large masses on examination proved to be double, oblique, reducible inguinal herniæ, and in March, 1889, the hernia on the right side was operated upon by the old method of simply dissecting out the sac, tying it high up, and leaving the pillars of the ring unsutured, to unite by adhesion, and closing the wound. In May of the same year, another surgeon operated on the left side by Dr. McBurney's method, and the patient remained in the hospital for a considerable time afterward. During this time he came under my care, and as his scrotum was exceedingly redundant, I amputated a portion of it, in August, and he was soon afterward discharged. Two months later, he tells us, both herniæ returned, *i. e.*, six months after the McBurney operation and eight months after the old operation, and he has been unable to wear a truss. He is naturally of a lax fibre, and is not a favorable subject for such operations; but he is extremely anxious to have something further done, particularly on the side where McBurney's operation was performed. Unfortunately, this is by far the most difficult side to operate on, owing to the matting together of the parts by cicatricial tissue, but I have decided to make the attempt, and shall perform the Macewen operation.

In this operation, as you know, the sac is exposed and if possible, dissected out without being opened. It is then doubled upon itself by means of a catgut suture passed through it, and is returned into the abdominal ring so as to make a mass between the fibrous tissues and the peritoneum. This mass is supposed to act as a pad, closing the internal ring. The two pillars of the ring are brought together by a peculiar form of suture to be hereafter described.

Having exposed the sac, you notice that I begin the dissection at its neck, as this is the part which is most easily recognized and most readily reached. The only serious danger is from injury to the cord; but by carefully tearing through the soft parts with the fingers or forceps this danger, as well as the amount of bleeding, is reduced to a minimum. The abdominal ring is large enough to admit three fingers, and we must first insert a sponge into the ring to prevent the descent of the intestine. It is well to avoid frequent sponging of the parts, as this imparts to all the tissues a uniform red color, and greatly increases the difficulty of distinguishing between them.

Macewen's suture is first passed through the conjoined tendon on the inner side in a direction almost parallel with its fibres, entering about one inch above the pubic bone and emerging half an inch below. This gives a loop half an inch long, which includes the conjoined tendon. Each end of the silk is then passed through the external pillar at points opposite to the insertions of the suture in the conjoined tendon. In this way the two pillars of the ring are brought together and made to overlap slightly. This method of suturing the pillars I consider the best yet devised, and I think that it, rather than the plan of rolling up the sac so as to make it plug the canal, is the essential feature of Macewen's operation. The plug is of very doubtful efficacy.

I propose to modify the operation in this case by separating the cord and having it held to one side during the passage of the suture, so that the pillars are brought together from the pubic bone upward, and the cord is thus made to pass through the upper instead of the lower angle of the wound. This plan, I believe, is of Italian origin, and was suggested by the fact that excellent results are obtained when castration is added to the operation for radical cure, allowing complete closure of the external ring. Whether equally good results can be obtained by simply displacing the cord, is as yet uncertain. In this case as the ring is very large, I shall pass a second mattress suture half an inch higher than the first, but otherwise similar to it. The sutures should not exactly follow the direction of the longitudinal fibres, because they would cut completely through, and even with this precaution they cut considerably. As a rule, these herniotomy wounds do best when a drainage-tube is inserted for a few days, but notwithstanding the size of the wounds and the amount of laceration to which the tissues are subjected, they generally heal very kindly. It is interesting to note that there is rarely any complication, such as hæmatocele, orchitis, or epididymitis.

The operation is now completed. The sac was very adherent to the ring, and at the posterior portion of the neck required a very difficult and tedious dissection, during which it was torn, necessitating a complete removal of the sac, and thus modifying the Macewen method. The large opening in the peritoneum at the neck of the sac was brought together with a continuous catgut suture, taking care to bring the peritoneal surfaces into apposition; then the remains of the sac were cut off, and the pillars of the ring united.

As regards the general question of the treatment of hernia by operation, I would say that a reducible hernia which is easily retained by a truss is better without operation; for the best statistics by all methods do not give more than fifty per cent. of permanent cures. There have been much higher percentages claimed for special methods by their authors or chief advocates, but it is suggestive that other operators cannot secure equally good results.

In this patient we shall make use of dressings which have been simply sterilized by steam, for after the previous operations the usual antiseptic dressings gave rise to a very troublesome eczema.

EXCISION OF A BUBO.

The next case which I present to you is that of a single man, twenty-four years of age, who comes to us with a mass of enlarged glands in the right groin. The only history of venereal trouble is that of an uncomplicated gonorrhœa three years ago; nor is there any history of a traumatism which would be likely to lead to such a condition. The etiology then, is obscure, but no more so than is often observed in the case of adenitis in other situations.

The present swelling was first noticed twelve days ago, and was followed by pain and redness of the skin. At present the mass extends half an inch below and two inches above Poupart's ligament, and in its longest diameter, which is parallel to Poupart's ligament, it is about three inches in length. There is an indistinct sense of fluctuation in the middle portion, and it is probable that some suppuration has already taken place; but in spite of this I think we can remove the entire mass and secure primary union. Such a result is much to be desired, for, you all know, that when these glands are allowed to go on to suppuration without removal, the process of healing is exceedingly tedious. Excision of such inflamed glands is much more popular now than formerly, the older surgeons fearing a wound of the femoral vein. Now that we know that the hæmorrhage from a wounded vein can be safely controlled by the lateral ligature or by a clamp applied in such a manner that it will not completely obstruct the venous current, this danger no longer deters us from operating.

The operation consists in making an incision in the long axis of the tumor, and turning back two flaps, protecting the wound as far as possible from contamination with pus by covering it with pieces of iodoform-gauze. Constant irrigation during the operation does more harm than good, by spreading the purulent discharge over all parts of the wound, and should not be employed until the mass has been entirely excised. Having dissected the flaps free from the glandular mass, it is advisable to reach the cellular tissue at the extremities of the incision. As you see, pus has already broken through the capsule of the gland and infiltrated the subcutaneus tissue. We begin the removal of the mass at the upper and more accessible portion, lift it from the fascia, and working underneath the tumor, clamp the large vessels as they appear. Remarkably large vessels are often found supplying these inflammatory growths. Sometimes the glands just above the femoral ring are involved, and it is then a difficult matter to dissect them from the vessels. Having removed the large mass, a few isolated glands are excised. The wound is now irrigated with 1-to-1000 corrosive sublimate solution, and, to secure a completely aseptic condition and at the same time to make slight pressure upon the interior of the wound, a strip of iodoform-gauze is introduced, over which the flaps are united. This gauze will be removed in twenty-four hours, and then properly-applied compresses will obliterate the cavity, and in all probability enable us to obtain primary union. Even if we should not attain this desirable result, the operation has greatly shortened the duration of the case; for the healing process takes place much more promptly after excision of the glands than after simple incision and curetting.

EXCISION OF HÆMORRHOIDS.

The next patient is a man thirty-four years of age, who has suffered from symptoms of hæmorrhoids for ten years, having lost a considerable amount of blood from the anus during the last four years. His general health is otherwise good. A ring of large external piles surrounds the anus, and within this outer circle is seen a large mass of slightly-protruding internal piles. At the posterior edge is a narrow ulcerating cleft which passes through the entire thickness of the mucous membrane, but there is no sloughing.

The patient being under ether, in the lithotomy position, the buttocks are carefully shaved and cleansed, and the sphincter ani dilated. The bowels have been emptied by laxatives and by an enema given two hours before the operation.

The operation which we propose to do is that of excision, introduced by Whitehead, which is the best for such extensive cases of the disease as we find in this patient. The only disadvantages of the operation are the rather abundant loss of blood which it occasions and the prolonged manipulation. With antiseptic precautions the danger of sepsis is very slight, even if primary union should not be obtained, and if the operation is properly done the cicatricial contraction will never occasion stricture.

A shallow incision entirely dividing the mucous membrane around the circumference of the anus just inside of the white line which marks the muco-cutaneous junction, is made with a scalpel, and the greatest safeguard is secured against cicatricial contraction by keeping well within this line. In this case the line passes over the irregular surface of the external piles and is not easy to follow, but with a little care the incision is completed. Next the internal hæmorrhoids are drawn down with the fingers inserted in the anus, and the incision is deepened with a pair of blunt-pointed scissors, cutting somewhat into the hæmorrhoidal tissue, until the longitudinal muscular coat of the bowels is recognized. This is also divided close to the anus, by successive snips of the scissors, until the outer surface of the mucous membrane is recognized. The latter is then easily separated from the surrounding tissues as far as is necessary, and drawn down. The most difficult part to dissect up is, in the male, the anterior surface, toward the base of the bladder. Clamps are applied to the bleeding vessels and about half a dozen require ligatures.

In this case about an inch and a half of the mucous membrane was drawn down, including all the spongy dis-

eased tissue, and then, beginning behind, it was divided beyond the limits of the diseased tissue with the scissors, only small portions being cut at a time, and the edge thus made being at once united to the edge of the external wound by a continuous, fine, silk suture. The principal bleeding vessels are usually found in the cut edge of the mucous membrane, but the hæmorrhage is easily controlled by the sutures. When the operation is completed a circular line of sutures is seen surrounding the anus. A large rubber drainage-tube about six inches long, wound with iodoform-gauze in the middle so as to make a spindle-shaped plug, is then introduced so that the thickest portion of the plug lies in the anus, and makes firm pressure upon the wound, thus preventing oozing of blood and favoring early union. The bowels are to be kept confined with opium for a week, if this can be readily done. If the bowels cannot be controlled, or if there is any objection to confining them, the stools should be made soft, but not fluid, and the anus and rectum carefully cleansed after each passage. The silk suture will be removed in ten days, unless it cuts its way out before that time. This patient has lost only a few ounces of blood, and although the operation has been rather tedious he is in good condition.

INTRACRANIAL LESIONS.[1]

By W. W. KEEN, M.D.,
PROFESSOR OF THE PRINCIPLES OF SURGERY IN THE JEFFERSON MEDICAL COLLEGE, PHILADELPHIA.

The programme proposes five questions for discussion. I feel that it will be better for me to leave the first two, concerning cerebral topography and the nature of the lesions, to the able neurologists who are to take part in the discussion, rather than to attempt to treat them so briefly and imperfectly as I should have to do in this paper. I shall, therefore, content myself with some observations on the last three questions, which are strictly surgical.

Before doing so, however, I desire to show to the members Mr. Horsley's new Rolandic-fissure meter, which I have lately obtained through his courtesy. Heretofore we have assumed that, as shown by Thane, the fissure of Rolando runs downward and forward at an angle of 67° with the middle line. Mr. Horsley's observations have convinced him that the angle varies with the shape of the head—that is tosay, with the cranial index. The higher the cranial index the greater the angle, the lower the index the lower the angle. Mr. Horsley assumes a standard for the cranial index of 75, as established by the caliper of Broca, and for the angle of the fissure of Rolando, 69° instead of 67°, and for every two integers of variation in the cranial index he assumes one degree of variation in the angle of the Rolandic fissure. Hence, if the cranial index is 77° instead of 75°, the angle for the fissure would be 70° instead of 69°, and if the cranial index is 73 the angle for the fissure would be 68°, and so on. Based upon this, he has devised the instrument which I show you, and which differs from the ordinary fissure-meters or cyrtometers in being provided with means to rotate the arm representing the fissure of Rolando.

INDICATIONS FOR OPERATIVE INTERFERENCE.

In considering the indications for operative interference in the brain, we must bear in mind first, the peculiar physical characters and relations of the brain and the mechanical and physical disturbances to which it is subjected; and secondly, its functional disturbances.

The brain differs from all other organs of the body in its physical characters and in its relations. It is softer, and its functions are more easily deranged by pressure, especially if the pressure increases rapidly. Its texture is more delicate, and the continuance and undisturbed performance of its functions are more vitally important to the ordinary activities of life than are those of any other organ. It is also more closely and firmly encased than any other organ. It is perfectly true that other organs have an envelope of greater or less resistance and density; for example, the eye is enclosed in the sclerotic, the testicle has the tunica albuginea, the structures in the palm are protected and to a certain extent enclosed by the palmar fascia, and the organs of the abdomen and pelvis, and those of the chest, are enclosed partly by bony and partly by muscular walls. If there is any increase in the contents, and, therefore, in the pressure within the eyeball, or within the tunica albuginea, either by inflammatory exudate, by suppuration, or by a new-growth, it is true that the envelope restrains them and produces compression, but the envelope will either yield or will be perforated with comparative ease; and, besides, even should the organs be destroyed, this does not involve life. If there is any similar increase in the contents, and, therefore, of the pressure within the chest, abdomen, or pelvis, there is plenty of room for an exudate, for pus, or for a tumor to form, without producing fatal pressure on the contained organs. If an abscess forms under the palmar fascia it can escape either under the annular ligament into the forearm, or posteriorly between the bones, and so relieve the pressure.

In the brain it is different. Not only is it a delicate organ, the integrity and functions of which are destroyed to a greater or less extent by any pressure unless quickly relieved, but the bony case which protects it is so firm and strong that, as a rule, long before it can be perforated and the dangerous pressure thus relieved, the brain will be rendered incapable of performing its functions, or life itself be destroyed.

In the case of increased pressure, both the brain and skull vary very much in their behavior according as the pressure increases acutely or increases slowly. For instance, when we have a rupture of the middle meningeal artery or acute hydrocephalus, the pressure will quickly cause coma and death; but in a case of chronic hydrocephalus, and sometimes of tumor, the increase is so slow that the brain accommodates itself even for a number of years to a gradually-increasing pressure, and if the patient be young, even the bones of the skull will yield without producing a fatal result until after a long interval. These considerations must have great weight in forming our decision.

In addition to these mechanical disturbances there are certain functional disturbances not caused by increased pressure, and probably the result of microscopical, and

[1] The opening of a discussion before the seventh annual meeting of the New York State Medical Association, held in New York October 22, 23, and 24, 1890.

even, as yet, undiscovered changes in the brain, which belong in another category.

Hence, in considering the question of operative interference from a clinical standpoint, the first great class of cases are those with *pressure-symptoms*, the second great class are those with what we may name, in default of a better term, *functional disturbances*.

In the first class, or *alterations producing pressure*, we may include abscess, tumor, effusions, and hæmorrhage. To these pressure-producing intracranial lesions (which are the only ones to be considered in the present discussion) should be added fractures attended by depression.

There is also another class of injuries, such as gunshot or other penetrating wounds, and lacerations of the brain-substance resulting from contusion, which produce very many of the symptoms that the lesions mentioned in the first class produce, as well as additional symptoms peculiar to these forms of wounds.

Among the *functional disturbances* may be mentioned epilepsy arising from traumatism and, therefore, usually attended by gross appreciable changes in the brain, though not necessarily by increased pressure; and, also, functional epilepsy in which there are no gross lesions. In the same class we should include inveterate headache, insanity, and other mental disturbances, and arrested development.

I will, therefore, briefly discuss, first, the indications for operative interference in the class of lesions attended by pressure-symptoms, and, secondly, the indications in those which are functional in character.

Lesions attended by increased intracranial pressure.—We can, in a few words, discuss the phenomena which attend intracranial pressure. First, the *intellectual function* suffers, and the patient becomes dull and stupid, and this stupor may gradually deepen into coma and total unconsciousness. Or, while consciousness is not affected, the faculty of speech may suffer, or ocular or auditory appreciation may be disordered. Secondly, there will be disturbance of *motility*, resulting either in paresis or paralysis of certain muscles or groups of muscles; for example, hemiplegia, monoplegia, or ophthalmoplegia. Thirdly, there may be changes in *sensation*, either over small or large areas. Fourthly, there will be changes in a majority of cases in the *optic disks*, and, possibly, in other parts of the eye-ground.

These phenomena will vary in detail, and will be more or less pronounced, according to the character of the case, and any one may be absent; but in no case can there be increased intracranial pressure to any extent without producing, wholly or in part, the picture I have so briefly drawn.

If to these pressure-symptoms we have added the phenomena peculiar to any one lesion, the diagnosis is well established. For example, in cases of tumor we will have the so-called cerebral vomiting, and, generally, headache and convulsions. In abscess we will very probably have a subnormal temperature and cerebral vomiting, a demonstrable cause in a long-standing otitis media, or a preceding severe fall or blow. In hæmorrhage from the middle meningeal artery we will have a history of a distinct traumatism, followed by that most important sign, an interval of lucidity, after which the coma will come on; while in ordinary apoplexy we have the age, atheroma of the arteries, and, what is usually equally important, the absence of traumatism. Besides all these general symptoms, there will be the localizing symptoms, which are of the greatest value.

If any lesion which produces increased pressure—which pressure, if unrelieved, will prove fatal—can be located, and, with reasonable certainty, can be differentiated from other conditions which produce more or less similar phenomena, and if the location is such as to render it accessible, our duty is clear: we should open the skull and remove the cause of the dangerous pressure, just as we open the abdomen, the chest, or the palm to remove pus, an effusion, a clot, or a tumor. The head has been too long regarded as something apart, something different from other portions of the body. What I wish to urge is that it should fall into line with the other cavities of the body. Subject, as it is, to the same diseases and injuries, it must be subject also to the same rules for surgical interference; modified in detail, it is true, but in no wise differing in principle.

It is perfectly true that our means for making a diagnosis are, in the head, greatly limited, as contrasted with other parts of the body. For example: inspection, as a rule, reveals nothing, whereas inspection of the abdomen, chest, or palm reveals a great deal. We are cut off from the use of touch by reason of the hard bony skull. For a like reason percussion is almost valueless, and auscultation useless. But we have, on the other hand, changes in far-distant organs which do not exist with other lesions. The paralysis of the hand, the arm, or the leg helps us to recognize and locate the lesion in the brain with an accuracy which, though not unimpeachable, is becoming more and more marked from year to year. So, too, the alterations of sensation in distant parts, and the lesions of the eye-ground are often equally valuable and equally certain.

Functional disorders.—There are, also, certain functional disorders in which we ought to interfere, and can often do so with advantage, though the indications in this class are as yet far less clear than in the case of pressure-producing lesions. Our ability to decide this often difficult question is also gradually but surely increasing.

The indications for operative interference may be thus briefly summed up: The disease must be, first, a grave danger to life, growth, or mental development, or must so destroy the comfort of living that life is not worth having. Secondly, it must be established in each case that the ordinary medical means have been exhausted, and that nothing further can be expected from drugs, diet, hygienic care, etc. Thirdly, the danger to life from an operation must not be so great that we may not run this reasonable risk in the hope of great improvement. It has been amply proved of late years that trephining *per se* is not an especially dangerous operation, provided that it be carried out with modern antiseptic precautions. When we go beyond simple trephining and open the dura it adds a little, but not a great deal, to the danger. When we take a further step and excise a portion of the tissue of the brain the danger is increased, and may be even greatly increased, but not to such a degree as to prevent our taking the step if a great gain is to be reasonably hoped for, and if there is great danger of deplorable and probably permanent mental and physical loss and deterioration without such interference.

Exploratory trephining.—In both classes of disorders, however, there are a considerable number of cases in which we are in doubt, either of the character of the lesion, its extent, its location, or of its physical characteristics. In these cases the same rule should hold good in the head as in other parts. If the danger is great, and especially if the result without interference is almost sure to be fatal, as is so often the case, intracranial lesions must now fall into line with lesions elsewhere, and we should perform exploratory trephining in order to make a correct diagnosis, and if the exploratory operation shows it to be possible we should remedy the condition found. The vital importance of the brain and the gravity of its lesions, while they should make us cautious, should also make the rule of exploratory operation even more imperative here than elsewhere.

This rule, however, must be modified in one important respect in intracranial lesions. In the abdomen, for instance, we need not be absolutely sure of the location of the lesions, for when the belly is opened its entire cavity is at our command. In the brain the conditions are very different. Exploration is limited to the exposed area and its vicinity. Hence the location of the lesion should at least be *probable* before we operate. But the extreme gravity of these intracranial lesions should embolden us to operate when the location *is* probable. If we wait until it is ascertained with certainty we must wait till a post-mortem examination clears up the diagnosis.

I should be loath to give the impression that I recommend, even to the best surgeon, reckless or indiscriminate trephining. Each case must be carefully considered, all the facts elicited, and the possibilities, the advantages and the dangers weighed; and if, having done this, the possibilities of gain outweigh the probable dangers, exploratory trephining is clearly indicated.

THE TECHNIQUE OF OPERATIONS ON THE BRAIN.

Shaving.—Under this head I wish to insist primarily on the need of shaving the head in order to determine the existence, number, and position of any scars. I have almost never shaved a head without finding several scars, with perhaps the history of only a single traumatism.

I cannot better illustrate this, I think, than by briefly narrating the following history of a case, the result of which I have also the pleasure of showing you in the person of the patient himself.

W. A., aged fifteen years, weight ninety-seven pounds, was seen in consultation with Dr. B. A. Watson, in Jersey City, September 28, 1888. A little more than two years before, the patient fell from a swing on to a stone step, striking on the top of his head and cutting the scalp badly. He thinks he was not unconscious. The wound healed in four weeks. Two months after the fall his first epileptic fit occurred. The bromides reduced the number of the fits to about one in a month, but when not taking bromides he had a fit nearly every day, usually beginning in the hands, but on which side could not be determined.

On shaving his head four scars were discovered, the principal one, an inch and a half long, beginning at the fissure of Rolando, one-fourth of an inch to the left of the middle line, and extending on the right side to one and one-fourth inches to the right of the middle line, the direction being slightly oblique and backward. A second but smaller scar was found one and three-eighths inches back of the fissure of Rolando, and two and seven-eighths to the left of the middle line. A third, still smaller scar was found at the same distance back of the fissure of Rolando and three-eighths of an inch to the left of the middle line. The fourth small scar was just above and one inch to the left of the inion. The size of the scars was in the order in which they are named, all but the first being small. All of the scars were slightly tender, the tenderness being most marked in the third. Under this scar an obscure indentation of the bone could be felt. Naturally one would suppose that the largest scar was the one acquired at the time of the only known accident to the patient which was followed so promptly by epilepsy.

It will be noticed that the history of the fits gave no indication as to the location of the cortical lesion. There had been no motor phenomena in the legs, though the principal scar was over the leg-centre, nor had there been any sensory or mental phenomena, such as word-blindness, word-deafness, agraphia, etc. The eye-grounds were normal. I should also add that the boy had been kept in the hospital under Dr. Watson's observation, but on no occasion could a fit be observed.

In view of the difficulty of localizing any lesion by the symptoms, and of the tenderness of the scars, I determined to excise the scars themselves and examine the bone, and, if I found reasons to do so, to trephine at any point where the bone seemed to have been injured. If the bone was found normal I would only excise the scars, and await the result.

On September 28, 1888, the scars were excised. The bone appeared uninjured and nothing else was done. For a short time after the operation the fits were absent, but then returned, and for months there were from one to four a week. Observation in the hospital again failed to determine their character, but the mother was now quite confident that the right side of the body was more affected than the left. Moreover, the boy had developed homicidal and suicidal tendencies. Accordingly, on September 7, 1889, at his own and his mother's urgent request, I performed the following exploratory operation:

Though the largest scar was chiefly on the right side, the symptoms seemed to point to the left side of the brain as the region of the trouble. I therefore trephined at the left end of this scar, half an inch to the left of the middle line, as close as I deemed prudent to the longitudinal sinus. A one-and-a-half-inch button of bone removed showed nothing abnormal in the bone. In order to determine next whether there was a lesion of the skull on the right side under the scar, I took Horsley's dural separator and swept it carefully backward and forward, hugging the bone very closely with the advancing edge, lest I should penetrate or tear the sinus, and thus I worked slowly from the left side across the sinus and one and a quarter inches to the right side of the middle line. I found the manœuvre not difficult and perfectly successful. I separated the sinus from the bone, the adhesions of the dura being much greater there than on either side. I also loosened the dura on the opposite side, and determined by the separator that there was no irregularity on the under surface of the skull cor-

responding to the principal scar, as far as one and one-fourth inches to the right of the median line and one and three-fourths inches from the edge of the trephine opening. The history and this examination convinced me that the two small scars on the left of the trephine opening were possibly, if not probably, the site of the trouble.

Accordingly I exposed the brain under my first opening. Here the brain appeared normal. Biting away the bone in the direction of the lesser scars and opening the dura the brain was seen to be abnormal over an area an inch in diameter and corresponding to the second scar. The abnormal area was whitish, as from an old inflammation, with, at one point, apparently a small cyst. In front and to the left was a distinct area of redness one-third of an inch in diameter. The whole of the abnormal area also was slightly depressed. Unfortunately the battery which we had would not work at the moment when we wanted to use it, and I was unable to determine the possible motor value of the convolution. As nearly as I could judge, it corresponded to the supramarginal, or possibly to the angular gyrus.

I then excised the abnormal part, which measured one inch antero-posteriorly, one and one-fourth inches transversely, and scant three-eighths of an inch in thickness. Immediately under this area, but half an inch deeper, I thought that I felt a spot of hardness which I removed with a Volkmann spoon. Examination of this afterward convinced me that my sense of touch was at fault, and that I had needlessly removed normal tissue.

The dura was now sutured, the large button and a number of small fragments of bone were laid upon it, and the wound was dressed as usual. The boy's highest temperature was only 100.6°, on one occasion, and in a week it fell to normal. His recovery was very rapid, a slight paresis of the right hand being the only apparent motor disturbance that remained.

Dr. Watson had the boy's eyes carefully examined, as I feared that I had injured the visual centre, or its radiating fibres, but there was neither ordinary blindness, word-blindness, nor apraxia.

Three months after the operation, I received a letter from the boy, expressing his thanks and adding that he had had no fits and was working for an express company. Since then he has followed the sea and been exposed to all its hardships. He has had no homicidal or suicidal tendencies. He has had only four attacks in nearly fourteen months, and the last one was more than three months ago. He has grown tall and robust. His hand is entirely well.

This case well illustrates the point I have made, that shaving the head is an essential preliminary to trephining. With the history of only one accident four scars were found, and the principal scar was evidently not the one corresponding to the cerebral lesion. In addition to this it shows that by the means I have described we can separate a sinus from the skull and reach across it to examine at least the bone, far away from the trephine opening.

Sublimate solution.—In connection with the preliminary preparation of the patient, I also desire to emphasize the fact that sublimate solution stronger than 1 to 2000, should not be used on the newly-shaven scalp. I have found that the ordinary 1-to-1000 solution pustulates the scalp; and even if there be no danger from it, it is the source of great annoyance which may easily be avoided. When the brain is exposed I discard all antiseptics and use boiled water only, not so much on account of the possible danger of poisoning as because the antiseptic lessens the reaction of the cortex to the electrical current.

Hæmorrhage.—The position of the patient is important. Mr. Horsley always operates with his patient reclining, not very far from a sitting posture, and I think that it is a good one, as it diminishes hæmorrhage, and hæmorrhage and shock constitute the two great dangers of cerebral surgery. The preliminary use of morphine and ergot diminishes the calibre of the bloodvessels and is certainly of value. The application of antipyrine and cocaine (ten per cent. solution) is of undoubted value, I think, in checking general oozing, but I doubt if it is of any more value than the application of hot water; and after all, it is not general oozing that troubles us so much as hæmorrhage from the large veins. Hence I think that both cocaine and antipyrine may be dispensed with.

For the arrest of hæmorrhage our chief reliance must be placed on the catgut ligature. With this the large vessels, and especially the large veins, should be double ligatured before division. After they have been cut it is very much more difficult to tie them. The hæmostatic forceps sometimes hold, but more commonly they tear away, which is followed by a renewed hæmorrhage, that is often controlled with great difficulty. The greatest care must be taken that the traction is equal upon each end of the ligature but that it is not too great—just enough to occlude the vessel and to retain their hold. To have room to cope with this formidable danger of hæmorrhage the opening in the skull must be ample. No vessel should be cut near the edge of the opening. If needful to cut it there the opening should first be enlarged by the rongeur forceps.

In addition to the ligature, hot water has yielded me very good results in many cases. But I am convinced that in at least one case I used the water too hot and produced cerebral disturbance which contributed to the fatal result. It should not be at a higher temperature than 120° F., if indeed so high.

Hæmorrhage from the superior longitudinal or from the lateral sinus is always alarming, and makes the operation speedily fatal, not only, I may even say not so much, from direct loss of blood as from the shock and the consequent loss of vitality of the nerve-centres. It recently happened to me to wound one of the large veins at its junction with the superior longitudinal sinus, in spite of the fact that I thought I was quite far enough away from that dangerous region. The reason for my being so unexpectedly near it was that in consequence of defective development the sinus was half an inch to one side of the middle line. I had recognized the defective development and had allowed for the displacement of the sinus, but as the result proved I had not allowed enough. The hæmorrhage was very severe, but was quickly controlled by a pair of hæmostatic forceps. During the later manipulations the forceps were detached, when another rush of blood came, and, although this, within a few moments, was controlled in the same way, the patient became moribund and died in fifteen minutes after the speedily-terminated operation, and about half an hour after the hæmorrhage

occurred. The amount of blood lost was perhaps between eight and twelve ounces, an amount that the patient could have lost from the arm or from a wound in the scalp, without such direful consequences. Hence the large veins should be carefully avoided, especially near the middle line where they empty into the sinus, and if they must be divided it should be only after two ligatures have been applied.

Should the sinus itself be wounded one of three courses is open to us. The first, adopted by my friend Dr. W. J. Taylor during the past summer, is to seize the edges of the sinus by the hæmostatic forceps, and let the forceps remain *in situ* for two or three days. The second is to pack the sinus, as many surgeons have done, and in most cases successfully. The third is to tie the sinus with two ligatures, one on each side of the wound, as has been done in a few cases.

The last manœuvre, however, is much more difficult in abundant hæmorrhage following a wound of the sinus, than as a preventive of hæmorrhage when the sinus is to be deliberately cut across. The deliberate ligation of the sinus has been done a few times, once in a very remarkable recent case related to me by Mr. Horsley, in which he removed a large part of the frontal and of the squamous portion of the temporal bone, tied and divided the sinus and lifted the frontal lobes, thus gaining access to an aneurism at the base of the brain, pressing on the optic chiasm, for which he ligated both carotid arteries; a surgical feat only equalled in its daring by the brilliancy of the diagnosis, which was verified by the operation. The patient, when I last heard, was recovering from the operation. Whether he will recover from the aneurism time only will show.

Not uncommonly after trephining, the cut edge of the bone bleeds very freely. To arrest this, Mr. Horsley informs me that he uses a paste or putty made as follows: Melt repeatedly one part of yellow wax and four of vaseline. Next, add carbolic acid one part to twenty of the wax and vaseline, and mix intimately. Then add sufficient white wax to make a mass that will be hard when cold, but that can be quickly softened by the fingers. With this (kept disinfected, of course) he "putties up" the vessels in the edge of the bone.

Drainage.—Whether drainage shall be employed, is an important question. In abscesses and other suppurative cases, continued drainage must, of course, be employed, but in ordinary operations I think the question must be decided in each case chiefly by the amount of hæmorrhage. If hæmorrhage has been arrested so that the wound is almost dry, drainage may be safely omitted. Mr. Horsley tells me that he has omitted drainage in all his recent cases. This is certainly the ideal operation, and the end toward which we all strive. In order, however, that we may do without drainage, the hæmorrhage must be checked to such a degree that only slight oozing if any remains when the wound is closed.

Exploring for abscesses.—As I have pointed out in former papers, the direction of exploration should not be obscurely described, such as "downward and a little inward and forward, etc.," but in a definite direction from the opening—*e. g.*, in the direction of the external angular process, the opposite pupil, an inch above the opposite external auditory meatus, etc. The reader then can locate the abscess when he knows the point of departure, the direction of the puncture and its depth. I have also given my reasons for preferring a grooved director to a needle in such exploratory punctures.[1]

Avoidance of shock.—I am persuaded by no little experience that in the head, more than in any other part of the body, we must bear in mind the lessons taught us by Dr. Cheever in his admirable paper on Shock, read before the American Surgical Association in May, 1888. He there urged that one of the important elements of shock was the time consumed in operation, and this applies especially to operations on the brain. A cerebral operation is always time-consuming, and this is especially bad in view of the prolonged anæsthesia. It is of the greatest importance, therefore, to abridge the time whenever it can be done.

Accordingly, I always raise the periosteum with the flap, instead of dissecting the two separately. Next, one of the most important elements in time is that required for trephining. The tendency has been of late to use very large trephines. I have commonly employed the one and one-half inch trephine, and I am persuaded that anything larger than this cannot be used with advantage. I have tried a two-inch trephine, but have found that it required a longer time than if I had made two or three one-inch trephine openings, and then bitten away the bone with the rongeur forceps to any further required extent. This arises from its becoming fastened in the bone, from the impossibility of adapting it well to the curved surface of the skull, and to the different thicknesses of the bone in different parts of its circumference. I have tried also to hasten the operation by using a surgical engine, but have found it not a practicable instrument. Mr. Horsley has recently devised an adaptation of the electric motor for working the trephine, with what success I do not know. The brace of a brace-and-bit has also been adapted to the trephine, with what advantage I cannot say. I am greatly inclined, however, to the opinion that the small trephine, one inch, or an inch and a quarter, and the later use of the forceps to bite away the intervening bridge, and afterward, if needful, still further to enlarge the opening, is the better practice, especially with a view to speed.

It is all-important also to use the battery in every case to identify the convolutions which are exposed, in order to determine in the human brain the motor value of the convolutions, if possible. In doing so, the graduated band of the fissure-meter should always be used to measure the distance of the convolution stimulated from the middle line, and from the fissure of Rolando or other well-recognized fissure. But while such determination of the motor value is important, it should not be made with too strong a current; the strength should be such as would freely move the operator's thenar eminence but no more. Nor should the time be wasted in repeated applications, further than is necessary to determine the facts. I mention the exact measurement to determine the situation of the stimulated area, because in a number of recorded cases, including some of my own, the value of such determination was practically lost by the inexactness with which the centres were located.

[1] Transactions of the Tenth International Medical Congress, and THE MEDICAL NEWS, December, 1, 1889, and September 10, 1890.

The dura may be sutured by either interrupted or continuous sutures, whichever will enable the surgeon to terminate the operation most speedily.

In addition to this the use of rest and of external heat from the very beginning of the operation, and of strychnine to prevent shock, and of alcohol, digitalis, and atropine to relieve it, have been forcibly advocated by Dercum,[1] and should certainly be tried.

Replacing the bone.—The question of closing the trephine opening by bone, is in my mind still a somewhat undecided one. In all the cases in which I have done it there is a flat surface instead of the normal arched contour of the skull. I have not been able to see, however, that it has produced any trouble, and it certainly acts as a valuable protective. In those rather obscure cases of headache and allied disorders, in which, perhaps, the chief value of the trephining lies in the alteration of intracranial pressure, the bone should not be replaced. In all other cases I have replaced it without any deleterious results, and I am inclined to think with advantage.

If the bone is to be replaced provision must be made beforehand for its care by placing it in a 1-to-2000 sublimate solution, and it should be the sole duty of one assistant to see that this is kept at a temperature of between 100° and 105° F., by means of hot water outside the cup or bowl in which the bone is placed. I have never had any trouble in replacing a disk as large as an inch and a half, and I prefer to do this than to spend time in chipping it up. But if the bone be greatly thickened it should not be replaced in mass, but either bitten into small pieces, or if the bone be diseased it should be rejected entirely. The suggestion of Senn to close the opening by means of decalcified bone is a valuable one, especially where there has been a prior loss of substance. It has also one marked advantage in that it can be better fitted to the opening than ordinary hard bone.

RESULTS.

These I will consider as to each disease or injury as briefly as possible. I shall not use the statistical method, but shall rather give the general conclusions I have reached, based both on my own experience and on a fairly thorough acquaintance with the literature of the subject. The topics, as announced, exclude from this paper the consideration of fractures of the skull, but I cannot help congratulating the profession on the development of cranial surgery in the treatment of these extremely serious injuries, and to urge that operative treatment shall be used more freely than formerly, not only with a view to the immediate saving of life, but to the prevention of later disorders, especially of epilepsy.

First, *Abscess.* No good surgeon will now hesitate to operate in a case of abscess of the brain. If there have been chronic middle-ear diseases or a serious local traumatism, followed by stupor and other evidences of intracranial pressure, paralysis of the oculo-motor nerves, choked disks, subnormal temperature and possibly hemiplegia, the surgeon should undoubtedly trepine, puncture, evacuate the abscess, drain and dress in the usual way. It is not so much a question of percentage as it is that every case which recovers is just one life saved which under the old method of treatment would inevitably have been lost. The question, "Where shall we trephine?" starts again the urgent cry for more accurate means of diagnosis, a cry that will not be suppressed until neurologists answer it satisfactorily.

Secondly, *Tumors.* Practically the same remarks will apply here as in abscess. Every case that recovers is a life saved from inevitable death in case we do not operate. The results have been on the whole, thus far, encouraging. Even very large tumors have been removed successfully, and a number of patients are still alive after several years. On the other hand, while a moderate number have died, there is again a not inconsiderable number that have suffered from a return of the original disease, and what is still more mortifying, there have been a number of tumors sought for and either have not been found, or have not even existed.

Here again we must ask most earnestly for the help of our neurological brethren, and happily we are not asking in vain. You will hear from some of them about to follow me the means for determining the location, the size, the number, and other characteristics of tumors and other intracranial lesions—means which become year by year more and more exact. We learn by our failures more than by our successes. Each case should be put on record, therefore, as a means of avoiding similar pitfalls. The technique of operation is now fairly satisfactory, though not yet perfect, and its dangers have been minimized, so that we no longer fear the operation. But what we need above all else to-day is a more accurate means of diagnosis.

Tumors will sometimes be met with that are too large for removal. It is extremely desirable that the neurologist shall be able to make a diagnosis of the approximate size of the tumor before the operation. But with our present knowledge it is too much to ask that this shall be done with absolute accuracy. Hence, unless it is almost certain that the tumor is too large it would be justifiable at present to attack it, for we may be mistaken, the tumor not being as large as had been anticipated and its relations with the brain much less intimate than had been supposed, and if so we may be able to remove it successfully: and if not, with modern methods in most cases the patient will recover from the operation, and in several recorded cases they have even been bettered by the attempted yet abandoned operation.

Again, it may be that tumors are erroneously suspected to be multiple, and hence not amenable to operation. Here, again, it is sometimes wise, inasmuch as tumor of the brain is a certainly fatal disease, at least to attempt the removal for the same reason as that just stated.

Tumors may be of such character that presumably they have infiltrated the tissues, so that a return will be certain after a very short interval. Here, too, we may be in error. Even in the case of a sarcoma, no infiltration may exist. I have lately had a case in point. Although the fall, which was the probable cause of the tumor, left no scar to mark the site of the blow, the diagnosis of the location of the tumor was exact. It was large, and the diagnosis had been that either one large tumor or two smaller ones existed. The nature of the tumor was doubtful but presumed to be tubercular, but the grounds upon which this diagnosis was made were not very certain.

[1] The Medical News, September 21, 1889.

The post-mortem examination showed that the tumor was large and situated in the area in which it was believed to exist, but even the slight manipulation for the removal of the brain produced auto-enucleation of the tumor. That it could have been removed by operation is very certain, and I have since deeply regretted that I declined to operate. The tumor was a sarcoma, and the microscopical examination showed that the walls of the cavity in which it was contained were not infiltrated with the sarcomatous growth. Whether, in spite of this, the removal would have been followed by permanent cure is doubtful, but the patient should at least have been given the chance.

Much doubt has been expressed as to the advisability of operating upon tubercular and syphilitic growths, but cases have been reported in which both were successfully removed. The argument in favor of operating on syphilitic growths is stronger than in the case of tubercular tumors, for the reason that tubercular tumors are more likely to be multiple than any other variety.

The depth at which a tumor lies is another important point. The deeper it is situated the less accessible it is to operation; and here, again, we must invoke the aid of the neurologists. I have operated on one case in which the evidence seemed to be pretty clear that the tumor was in the cortex of the angular and supra-marginal gyri. At the operation it was found to be underneath these gyri, but at such a depth as to render its extirpation impossible, and the patient died a few hours after the operation.

Perhaps the greatest opprobrium of cerebral surgery and the best proof of the need of more exact means of diagnosis is in the number of operations in which either no tumor was found, or it lay in a wholly different position from that which had been diagnosed. I have never yet operated upon a case in which no tumor existed, but in one case the tumor was believed to be in the cerebellum, and the post-mortem examination showed that it was in the floor of the third ventricle.

In one locality it is a question whether tumors, unless they are small and accurately diagnosed, can be removed with safety—namely, in the cerebellum. A few such have been operated on, but all proved fatal. In one case[1] I suspected a tumor and sought it, not by a formal operation, but by a slight opening in the skull and probing of the cerebellum, both through the exposed lobe and obliquely into the opposite lobe without any resultant injury. The post-mortem examination showed that the tumor was a soft sarcoma, and that my probe had passed through it without detecting its presence. But had I detected it and attempted its removal, the large vessels supplying it and its intimate relations to the fourth ventricle make it probable that the patient would have died upon the table. The structures in the neighborhood of the cerebellum and the fourth ventricle are so vital that I doubt whether we shall be able to cope with their dangers successfully, except, as I have said, in the case of small tumors, situated well back in the cerebellum and indicated by such symptoms that we can diagnose them accurately.

Epilepsy.—The most frequent disorder in which our advice is sought as to the propriety of operation is epilepsy. In cases of traumatic epilepsy the results have been, on the whole, very encouraging. A considerable number of cases are on record, some of them very severe, in which the patient was entirely relieved of his dreadful malady; and, while idiopathic epilepsy has not yielded such good results, they have been sufficiently encouraging to warrant our persisting to operate in well-selected cases.

The results, I think, in general, may be summed up as follows. First: Taking one operator with another, a small percentage of cases will die from the operation. Secondly: In a small but somewhat larger percentage absolutely no result, good or bad, will follow recovery from the operation. Thirdly: In a large percentage of cases the patient, while not cured, will be benefited, the fits persisting, but with lessened frequency and violence. Fourth: Perhaps in twenty-five per cent. more or less the result will be practically a cure. If I may judge from the feelings of the parents and of the patients also, the opinion of those most interested is that the operation is justifiable, because the malady is so dreadful. Even if the patient is not benefited no harm is done, and whether he is benefited, cured, or dies, both he and his friends are content.

One thing especially should be noted. It has been used as an argument against operating that the removal of diseased tissue will result in a permanent paralysis, and that the patient pays dear for the cure; and that he may not only be cured but have the additional affliction of a useless arm or leg. This is not my experience. The paralysis which follows the excision even of a motor centre is only temporary. One of my patients whose hand was absolutely paralyzed immediately after the operation, had so far recovered its use after between three and four months that he could play baseball; another is able to use his hand well though it is slightly paretic; and a third is scarcely conscious that his hand was ever affected.

Whether, as is most likely, this recovery of function is due to the development of the bilateral function of the corresponding centre on the other side, or whether, as seems less likely though not impossible, new cerebral tissue has been developed, is not certain. The recent experiments of Prus,[1] Salviati,[2] and Gilman Thompson[3] show that portions of the cerebral cortex can be successfully transplanted from one animal to another. Possibly this may hereafter lead us to a more perfect restoration of motor function, by a similar transplantation from an animal to man.

Hæmorrhage from the middle meningeal artery.—Hæmorrhage from the middle meningeal artery even without fracture is now an accident amenable to operation and not uncommonly with success. I would especially urge that if the clot is not found by the first trephining a second trephine opening should be made, as is advocated in the able paper of Krönlein.[4] The site of these openings should be, as he has indicated, first one inch behind the external angular process at the level of the upper border of the orbit, and, failing to find the clot, secondly at the same level and just below the parietal

boss. The two openings give access to the two branches of this vessel.

The accident, if untreated is necessarily a fatal one. The operation, while by no means always a success, has resulted most brilliantly in several cases, and its lesson is evident: that the surgeon should always at least endeavor to save life by trephining and ligature of the bleeding vessels.

Surgery of the lateral ventricles.—I have so recently and fully considered the question of the surgery of the lateral ventricles[1] that I need not here repeat what I have said in that paper, saving to urge that a trial be given to the method I have advocated, until its value or its worthlessness shall be determined.

Inveterate headache.—Cases of inveterate headache which have resisted all other known means and still make life unbearable are as yet in the category of undecided questions, judged by the results. Enough cases, however, have been recorded to show that trephining is well worth a trial until the value of the operation shall be determined.

Mania.—In mania following traumatism it is certainly right to attempt relief by a carefully conducted exploratory trephining. Should death follow, it is a relief from a condition worse than death, and should relief and cure follow, as has already been the fact in a number of cases, it is a brilliant triumph. The evidences of the site of the injury guide us to where to operate.

Arrested mental development.—In cases of imperfect mental development, from arrested growth or, as in the case of Hare and Felkin,[2] from a cyst following an injury, the result of operation has been such as to encourage us, but excepting those cases which follow traumatism I cannot look with great encouragement to the future of cerebral surgery in this direction. Whether the remarkable result of craniectomy recently recorded by Lannelongue[3] will show that we ought to give room for the growth of the repressed organ, must, in the absence of further evidence, remain for some time an open question. The same remarks apply to trephining for general paralysis.

DISCUSSION.

Dr. James J. Putnam, of Boston, called attention to the relative value of certain signs of cerebral tumors, especially of such tumors as are a little outside of the familiar areas of the central, temporal, and occipital zones, and only infringe upon these, so that the symptoms would be liable to occur rather late in the progress of the case. It is generally admitted, he said, that monoplegias and localized hemiplegias are more valuable as localizing signs than monospasms and localized convulsions. A paralysis gives fairly positive evidence that the whole cortical area corresponding to a set of movements is destroyed; whereas, a localized convulsion may be due to an irritative lesion in the tissues adjoining the area in question, or at a distance from it, or even to an unstable nutritive condition of the cortical area without gross lesions.

In accordance with a similar course of reasoning, the speaker said that a distinction could be drawn between the different localized paralyses on the one hand, and localized convulsions on the other. Those functions of the brain which are relatively highly specialized and complex in character, are more likely to suffer disturbance than the less highly specialized and complex functions. Thus, Hughlings Jackson long ago pointed out that, given an irritation of the arm- or in the leg-centre leading to an epileptic attack, the attack would be most likely to begin in the thumb or fingers in the one case, and in the toes in the other.

According to this statement, a localized convulsion or paralysis of the shoulder would have a greater localizing value than a convulsion of the muscles of the hand, and hence would indicate the presence of an irritative lesion of the shoulder-centre more surely than a convulsion of the muscles of the hand would indicate a lesion of the hand-centre. This the speaker believed to be true. Ordinarily an error in connection with this would not be of much importance, as the operation would in all probability be successful, and the mistake never be discovered. The mistake would be important, however, if the convulsions were caused by pressure transmitted from a considerable distance, or by œdema or anæmia. This occurred in a case of the speaker's, in which Dr. H. N. A. Beach had operated as a last resort for a supposed tumor of the frontal region. He was led to this diagnosis by the occurrence of repeated attacks of speechlessness, which were wrongly interpreted as motor aphasia, and by a twitching of the fingers of the right hand, associated with slight but distinct paresis of the extensors of the fingers. At the autopsy the tumor was found at the inferior parietal lobule just in front of the angular gyrus, and separated by a space of three-fourths of an inch from the motor area. In another case there were convulsive movements of the shoulder, not attended by loss of consciousness, and occurring only once late in the case. Had movements occurred several times, it would have been considered proper to operate, and had this been done, the tumor would have been found directly in the field of operation. The speaker wished to emphasize his belief that this shoulder convulsion might have been considered as a localizing sign of great value.

Direct and important physiological evidence also is not wanting in favor of the statement that the cortical areas corresponding to highly-specialized movements have a special irritability. Thus, Panett found that the visual centres in the case of a dog were more irritable to electricity than were the other areas; so much so, that it was a disturbing element in some of his experiments.

A patient was recently treated at the Massachusetts General Hospital, in the service of Dr. A. T. Cabot, for a severe fracture of the occipital bone, leading, as the autopsy showed, to multiple contusions and small hæmorrhages with softening, over the surface of both hemispheres. The speaker carefully examined the brain, and found that the motor areas of the hands were not involved in the gross lesions; and yet the night before the patient's death, although able to move his arms freely, he showed a striking paralysis of motion of the fingers, and especially of the extensors.

On these grounds, and in accordance with the principle he was trying to illustrate, Dr. Putnam suggested

that spasm of the extensor muscles and paralysis of the flexors are probably more valuable than the reverse condition as localizing signs of the cortical lesion.

The *comprehension* of speech is certainly a more fundamental element of the language-function than the *power* of speech, for it is earlier and more readily acquired, and requires less subtle and perfectly-adjusted cerebral activity for its maintenance, and the so-called auditory aphasia or loss of the comprehension of spoken language is a more valuable localizing sign than motor aphasia. The doctrine of sensory aphasia would be more generally recognized were it not for the strong influence still exerted by Broca's remarkable discovery, which, in the minds of most medical men, chains every disorder of the speech-function to the notion of a lesion in the third frontal convolution. As a matter of fact, the function of speech is liable to betray the presence of cerebral disorders, either far from or near to the motor speech-area. Not only does the loss of auditory impressions entail aphasia, but the loss of visual impressions may have a similar effect.

The speaker then briefly referred to some interesting experiments on the effect of quickly recurring stimuli upon the irritability of different cortical areas.

Unilateral neuritis has been considered by some to be of significance as indicating the presence of a tumor of the opposite side of the brain; but, in Dr. Putnam's experience, and in that of a number of others whose cases he had found recorded, the reverse condition was present.

DR. CHARLES K. MILLS, of Philadelphia, said that the failures and errors in the present method of localizing intracranial lesions are caused as follows: First, by attaching too much importance to certain classes of symptoms, which are regarded as determinative of the site of the lesion, as, for example, the so-called signal or initial symptom. Secondly, by considering symptoms of late invasion only. Thirdly, by attaching relatively too much importance to motor localizing symptoms. Fourthly, by overlooking multiple or diffused lesions. Fifthly, by operating on incurable cases of arrested development. The so-called signal or initial symptom of brain tumors, while of great value, has sometimes proved misleading. The motor signal symptom has been made use of in a large number of cases to guide the surgeon, and sometimes successfully, but almost as often unsuccessfully. It should be remembered that in every case of unilateral spasm and of monospasm, whether reflex, dural, nephritic, toxic or hysterical, the spasm really or apparently begins with an initial symptom in the limb or face. This may indicate that the beginning of the cerebral discharge occurs in the area of the cortex which controls the movement, but it would be unwise to operate with such an indication. Occasional conjugate deviation of the eyes and head has been used as a guide to operation, and is one of the errors into which a thoughtless neurologist might be led.

In making a diagnosis as to the existence of hæmorrhage, we must depend largely upon general symptoms. This is also true of the diagnosis of tumors, and still more true of abscesses. A number of mistakes have been made in trephining for tumor or abscess by the operator being too much guided by motor symptoms, which were really the result of the diffusion of the lesion to the motor areas.

In not a few cases of cerebral abscess, sensory or special symptoms might cause a decision in favor of operating, and at the same time might not properly guide the operator to the seat of the lesion. All active localized symptoms of the brain, the result of mastoid or aural disease, except, perhaps, word-deafness and left-sided affections, are the result of the extension of suppuration. Few physicians have escaped from mistakes in cases in which a large lesion either in the frontal or temporal lobe caused prominent motor symptoms by pressure, either upon the motor tracts in the capsule or upon the cortical areas and their tracts. In one case of this kind, all the symptoms pointed to brachial or crural monoplegia, due to tumor with intercurrent hæmorrhage. The autopsy showed a tumor with a large hæmorrhage, strictly confined to the right temporal lobe, but evidently causing great pressure. Several recorded failures were the result of overlooking the pressure of multiple or different lesions.

Operating in cases of tubercular disease of the brain, vessels, or membranes, has also been a source of error and cause of failure. It is, in most cases, an error to operate, guided by certain localizing phenomena, in the spastic and paralytic, congenital and early infantile affections. A careful review of the surgical operations guided by the rules of localization in whole or in part, show that probably the greatest success during the last few years has been in trephining for hæmorrhage. In traumatic cases failures have occasionally resulted, and for several reasons, chiefly because the fact is not fully considered that in many cases of depressed and non-depressed fractures hæmorrhages take place, not only at or in direct connection with the place of injury, but also at various positions more or less remote.

DR. JOHN B. ROBERTS, of Philadelphia, said that the impulse given to cerebral surgery by the wonderful results of the last few years, has been the means of saving life in many cases of traumatism, but he believed it had slain about as many of those who had been the subject of obscure lesions. It is well that the pendulum has swung the other way, and that cases are being selected with greater care and judgment. In cases of foreign body, such as gunshot wounds of the brain, it is generally agreed that operative interference is indicated, and that an exploratory trephining should be performed, not only for the removal of the foreign body, but also for drainage, which, after all, is often more important.

The speaker then referred to the importance of keeping the nose, pharynx, and similar channels leading to the seat of fractures of the skull as nearly aseptic as possible, for he thought that neglect of this precaution has been the cause of many cases of suppuration within the skull.

When symptoms of abscess are present, even if there are no clinical evidences of ear-disease, it is proper to open the mastoid process and search for a purulent focus before exposing the brain. If this should be found, it would make it almost certain that there was an abscess in some portion of the temporal lobe, and then an exploratory trephining would be indicated.

The jamming in the bone which occurs with the use of large trephines can be avoided by the use of the "segment trephine," which the speaker described some time ago, but much of the difficulty is frequently

due to the fact that the trephine is not sharp. The ordinary trephine cannot be rendered surgically clean except by baking or steaming, but by employing the "aseptic trephine," which has no centre-pin, this difficulty can be overcome.

The results of these operations are often very brilliant, as in those reported by Macewen, of which one patient was living eight years after the removal of a tumor, and another one year after the removal of a tuberculous growth. The most unsatisfactory cases are those of epilepsy, except cases of traumatic origin, which are often treated most successfully by operation.

Dr. Joseph D. Bryant, of New York, in considering the question as to the present means of localizing intracranial lesions, limited the term *lesion* to abscess, hæmorrhage, depressed bone, and tumors of intracranial origin. He classified the means of localizing these lesions into topographical, physiological, and instrumental. The topographical means relate to the connection existing between the established landmarks and lines of the cranium that bear a positive relationship to the superficial parts of the encephalon, many of which parts have had definite functions already assigned to them. The physiological relate to the establishment of the site of the pathological process by studying the deviation of the function of a part from the normal as the result of a local disease or injury. The instrumental means are largely subsidiary, and their application is often more of an experimental than of a practical character. The speaker then described several cases bearing on the subject, and concluded with the following summary:

(1) That a small and presumably circumscribed injury of the brain at the upper end of the fissure of Rolando may excite a cerebral disintegration sufficient to involve the motor centres associated with this fissure, without causing notable constitutional symptoms. (2) That aspiration of the brain as a means of diagnosing the extent or situation of an abscess is of uncertain utility, even when a moderately large needle is used, and that the employment of the ordinary hypodermic needle for this purpose is entirely unreliable and misleading. (3) That extensive fissures may occur at some distance from the seat of the violence causing them, and that their existence may remain unrecognized unless carefully searched for. (4) That extensive and fatal complications may be caused at a considerable distance from the seat of an apparently innocent injury of the skull. (5) That when paralysis involving the motor areas of the brain follows an apparently trivial injury of the head, an operation at the seat of these areas is indicated if only for the purpose of exploration. (6) That the removal of a compressing blood-clot is not necessarily followed by improvement of the symptoms of compression, and that if the brain does not soon resume the normal relation with the skull, death will ensue.

In one of the cases cited, the patient immediately after being struck on the head with a bottle, lost the power of speaking his own name, but was able to write it as well as the name of his assailant. When admitted to the hospital, he had forgotten his own name, and that of many things. An examination of the injury disclosed a small circumscribed depressed fracture of the skull located near the lower end of the fissure of Rolando. On the following day the depression was elevated, and all the aphasic symptoms disappeared. This case impressed the fact that the effects of a circumscribed compression due to trauma may be limited to one motor centre only.

Dr. Thomas H. Manley, of New York, divided intracranial lesions into two classes, namely, those of extrinsic and those of intrinsic origin—those arising from violence or mechanical influence, and those resulting from pathological changes within the skull. Dr. Manley's remarks were chiefly confined to traumatic lesions, but with slight modifications they were applicable to intracranial new-formations. There may be grave symptoms, he said, from injuries of the head, without the skull being implicated; and, on the other hand, the bone is often shattered into many fragments and driven through the meninges and into the brain, and yet no single symptom indicative of cerebral disturbance be manifest. This is frequently observed in military surgery, and is often very conspicuous in young children. In general, in cases of depressed fracture, trephining is indicated and is readily performed, but if the fracture is situated over a sinus it may cause sudden and even fatal hæmorrhage. He thought it poor practice to replace the bone that is removed, for of all parts of the osseous system, the skull has the feeblest power of regeneration, and the union with the adjacent parts which seems to take place is probably not osseous.

The question of hæmorrhage is important, and he believed that in his fatal cases this was a prominent factor. As hematomata of moderate size are as readily absorbed here as in other parts of the body, in cases of intracranial lesions with intracranial hæmorrhage, trephining for displacement of the clot is not only unnecessary, but is illogical and dangerous. Within the last year he has trephined four children who had general traumatic meningitis; two being trephined in consequence of the diagnosis of cerebral abscess. The brain-substance was deeply penetrated, but nothing was found, and the post-mortem examination on the following day showed only general meningitis. The other two cases did not survive over forty-eight hours. The loss of blood, together with the lethal action of the anæsthetic, materially shortened their lives. He has found meningitis very prone to develop after cranial injuries in young children when antiseptics are used; and since he has discarded them in these cases, and kept the head well covered with ice or cold lotions, it has been much less frequent.

When the use of the trephine causes much laceration of the brain-substance, the exposed part gradually disintegrates, and is absorbed, which may be followed by symptoms of impaired mental powers. When the area of destruction is small and unimportant, a young and healthy patient may completely recover.

Of all the organs in the body, there is none in which the effects of an anæsthetic are so evident, both by subjective and objective phenomena, as in the brain. When a patient enters the lethal stage during etherization the vascularity of the brain is enormously increased, as shown by the great increase of the volume, the convolutions rising and crowding into the aperture made by the trephine. As the ether is withdrawn the brain becomes less hyperæmic, and returns to its normal

dimensions. One can easily understand that manipulations involving the brain under these circumstances must be always attended by serious difficulties, the vessels giving way under the most trivial disturbance, and causing profuse hæmorrhage. Independently of the effects of the anæsthetic on the vascularity of the brain, is its influence on the nerve-centres, when the brain is injured or diseased; so that ether cannot be otherwise than harmful.

THE CONTROL OF HÆMORRHAGE DEEP IN THE PELVIS, WITH THE REPORT OF A CASE OF OVARIOTOMY.

By CHARLES P. NOBLE, M.D.,
SURGEON-IN-CHIEF TO THE KENSINGTON HOSPITAL FOR WOMEN, PHILADELPHIA.

At times it is desirable to have a method of controlling hæmorrhage deep in the pelvis, in addition to the usual methods of securing the bleeding point. Owing to the relative inaccessibility of the region, and to the fact that the hæmorrhage itself tends to obscure the field, it is often extremely difficult or is impossible to employ satisfactorily the ordinary methods of hæmostasis. When it becomes necessary to ligate fleshy pedicles, subsequent shrinkage of the tissue within the pedicle may permit bleeding. Also, when there are extensive raw surfaces on the broad ligament produced by the separation of densely-adherent tumors, or left after the removal of the ovaries and tubes disorganized by suppuration, and in certain cases of extra-uterine pregnancy, free oozing may occur, and is difficult to control by strictly local methods. In such cases stuffing the pelvis with gauze has been employed. In hysterectomy, with the intra-peritoneal management of the stump, and in myomectomy, the danger of secondary hæmorrhage is well recognized.

In such cases securing the ovarian and uterine arteries gives a control of the situation not attainable in any other way. In the case of oozing fleshy pedicles it is a necessary measure. The same is true of oozing raw surfaces on the broad ligaments. In case of active hæmorrhage, primary or secondary, in which the bleeding point cannot be readily secured, the ligation controls the hæmorrhage and gives time to secure the bleeding vessel. The method is particularly valuable when the broad ligament is fixed by exudate.

This procedure was brought to my attention by seeing Dr. H. A. Kelly employ it in several cases, and with very gratifying results. Since then I have adopted it twice with great satisfaction.

Mrs. X., aged thirty-seven years, has had three children and one miscarriage. Her health was good until January, 1890, when she had *la grippe*. Following this she suffered very much from bronchitis and dyspepsia, and rapidly lost strength, being finally obliged to go to bed. In March she came under the care of Dr. Minich, who, finding an abdominal tumor, referred the case to me.

I saw her April 7th, and found her a large, fleshy, very anæmic woman, with hurried, anxious breathing and quick, feeble pulse. The belly was enormously distended by a tense fluctuating cyst. Operation, after preparatory treatment, was advised, and she entered the Kensington Hospital for Women, April 14th. A severe cough with consolidation of the middle lobe of the right lung immediately developed. The temperature ranged from 99° F. in the morning, to 103° F. at night. Profuse night-sweats and orthopnœa prevented sleep. The condition of the lung, following *la grippe*, it was thought explained the general symptoms. Under stimulating expectorants, digitalis, stimulants and food, with counter-irritation over the chest, the lung slowly cleared up, the cough disappeared, and the appetite improved, but the septic symptoms remained the same. In spite of the entire absence of abdominal pain, no rational explanation of the sepsis was apparent except some inflammatory process connected with the cyst. Accordingly, notwithstanding the bad general state of the patient, section was made, under chloroform, May 10th.

On tapping the cyst fifteen quarts of puriform material were discharged. The cyst, which was non-adherent, was delivered and found to be deeply situated between the layers of the right broad ligament, and to require ligation over a surface of eight inches. A series of twenty-two interlocking ligatures was applied from the pelvic wall to the uterus, in the form of an arc owing to the deep development of the tumor.

The tumor was now cut away. As the tissues were very vascular, to provide further against hæmorrhage the ovarian and uterine arteries were ligated in their course. A ligature was passed through the broad ligament on one side of the ovarian artery, and back through the ligament on the other side of the artery, and the vessel was thus securely tied. A ligature was then passsd through the broad ligament close to the uterus, and again through the ligament to the distal side of the row of ligatures in the stump, and in this way the uterine artery was secured.

A sessile cyst of the left ovary (containing about a quart of fluid) with a broad attachment, likewise required a series of interlocking ligatures, fourteen in number. The left ovarian artery was tied in the same way as the right one. Hæmorrhage was in this way entirely controlled, and scarcely a drop of blood oozed from the extensive raw surface.

The extent of the raw surface was a source of anxiety, offering, as it did, such possibilities of intestinal adhesions. At the suggestion of Dr. Kelly the stump of the right pedicle was disposed of by stitching the raw surface of the broad ligament at uterine cosine, to the raw surface at the infundibulo-pelvic ligament. A few stitches along the anterior face of the broad ligament brought the raw surfaces nicely in apposition.

Very thorough douching completed the opera-

tion. Water had been freely used during the operation to wash away puriform material, some of which had escaped from the cyst. A drainage-tube was introduced and the patient put to bed.

The operation lasted two hours, the longest operation in my experience. Almost the entire time was consumed in introducing the ligatures, as the other steps in the *technique* required but a few minutes.

The patient steadily improved and all septic symptoms quickly disappeared. The drainage-tube was removed after thirty hours and the sutures after six days. On the eleventh day, symptoms of inflammation about the right stump appeared, and continued until pus was discharged through the incision on the twenty-first day. The subsequent history of the patient has been one of rapid recuperation.

The case is reported because of its bearing on the questions of pelvic hæmostasis and the manner of disposing of extensive raw surfaces. It is also of interest as a further illustration of how, under the most desperate circumstances, patients will recover, to encourage the surgeon to extend to others, under similar circumstances, the resources of surgery.

HYPERTROPHY OF THE PHARYNGEAL TONSIL AS A CAUSE OF DEAFNESS, WITH THE REPORT OF A CASE.

By LAURENCE TURNBULL, M.D., Ph.G.,
AURAL SURGEON TO THE JEFFERSON MEDICAL COLLEGE HOSPITAL, PHILADELPHIA.

The pharyngeal tonsil is a soft mass of lymphoid tissue, in health measuring not more than seven millimetres in thickness. It occupies the roof and the upper part of the posterior wall of the naso-pharynx, reaching from the posterior margin of the roof of the nasal cavities to the edge of the foramen magnum. Laterally it extends into Rosenmüller's fossæ, and to the Eustachian tubes. It is always present, varying in size in different individuals, and occurs in folds which are either longitudinal, or form a regular network; more rarely it is a cushion with small round elevations.

The pharyngeal tonsil is covered with ciliated epithelium, and is composed of acinous glands and numerous follicles of lymphoid tissue, but differs from the true adenoid vegetations in not being pedunculated or giving to the finger the sensation of a soft, cushion-like mass.

The normal secretion from the pharyngeal tonsil consists of an absolutely transparent, somewhat viscid mucus of the appearance and consistence of the white of an egg, which becomes changed in diseased conditions. At the present day Luschka's idea of a normal pharyngeal bursa is abandoned, and it is only the morbid hypertrophied condition which resembles a bursa.

The simple form of hypertrophy of the pharyngeal tonsil is distinguished by characteristic features perceptible both to sight and touch. Explored by the finger a smooth, elevated, rounded mass is felt in the vault of the pharynx, encroaching upon the Eustachian tubes and upon the choanæ, so that the upper boundary of the posterior nasal fossæ cannot be defined. The sensation is entirely different to the touch, as I have before stated, from that which is felt when post-nasal growths are encountered.

When viewed in the rhinoscopic mirror in the case of a girl of sixteen years, it appeared as a solid rounded mass encroaching upon the Eustachian tube of the left side and pressing upon the orifice.

To the otologist the chief interest of the pharyngeal tonsil when diseased lies in its interference with the Eustachian tubes, which may be compressed by the growth. The following illustrative case had also a chronic rhinitis, with some enlargement of the faucial tonsil of the same side.

There was marked deafness on both sides, the hearing distance of the right ear was $\frac{9}{XXII}$, and of the left, the side on which the Eustachian tube was encroached upon by the tumor, $\frac{5}{XXII}$.

The membrana tympani of the right ear was retracted and dull; the auditory meatus was inflamed and irritated by an old ulcer near the edge, and was reduced in size by an old cicatrix following a perforation.

The Eustachian tube on each side was almost impervious to inflation by Politzer's method. There was also an ulcer in the left nasal cavity.

The treatment consisted of a cleansing spray to the naso-pharynx, an ointment composed of ten parts of nitrate of mercury to twenty of oxide-of-zinc ointment to the ulcer in the nose, and iodine and iodide of potassium dissolved in glycerin, to the faucial tonsils. To the enlargement of the pharyngeal tonsil, repeated applications of styptics were made. This treatment was kept up for weeks, with only partial reduction of the tumor, so that avulsion of the mass had to be resorted to.

After a month's treatment, the ulcer in the nose healed, the rhinitis was cured, and the ulcer near the membrana tympani had closed. By careful inflation and the use of a twenty-per-cent. solution of menthol in cosmoline, applied to the membrana tympani, at first every day for a week, then every second day, the membrane cleared so much that a partial reflex was secured. After that, inflations with air medicated by ether kept the parts free. The hearing was improved to $\frac{18}{XXII}$, while by the removal of the tumor and subsequent treatment the hearing became normal. No evil consequences resulted from the operation and cicatrization followed, while all traces of the tumor disappeared in a month after the operation.

AMPUTATION AS AN ORTHOPÆDIC MEASURE.[1]

BY AP MORGAN VANCE, M.D.,
SURGEON TO THE LOUISVILLE CITY HOSPITAL, AND TO STS. MARY AND ELIZABETH HOSPITAL, LOUISVILLE, KY.

THE introduction of amputation as an orthopædic measure is out of the recognized lines of treatment, but as we are expected to relieve our patients of crippling and deformity, it is obvious that if amputation in some cases is the best, and often the only way this can be done, the operation may become orthopædic.

Even the most conservative among us occasionally meet cases in which the question at once arises, Would this patient be better off without this deformed foot or subluxated tibia? But, few of us have ever removed a useless limb in order to substitute a useful artificial one. In the past ten years I have had under my care a number of cases in which there was no doubt in my mind that amputation, performed only for convenience, was better than any other treatment. Possibly some will say, You should refer such cases to the general surgeon. But I think that the mechanical and special training of the orthopædist peculiarly fits him to deal with these patients. Who should be better able to determine the proper method to be used or the point of selection in given cases—the general surgeon or the orthopædist? The orthopædist, of course, for he should know all about the mechanism of the prothetic apparatus. The general surgeon learns how to do the operation by a given method, but rarely knows whether an artificial leg is made of cork, wood, or what not, or when doing an amputation, bears in mind the subsequent comfortable and useful adjustment of the prothetic apparatus. He rarely knows that it is absolutely necessary to have from four to six inches space above the ankle-joint for the attachment of an artificial foot, and consequently we often meet men struggling through life with stumps the result of amputation just above or through the joint. The same may be said of the knee. An amputation through this joint is an abomination to the artificial-leg maker and a never-ending trial to the patient.

At least three inches should be left for the proper adjustment of the apparatus. We daily meet cripples who would be rendered more comely, comfortable, and useful by means of an amputation and the fitting of an artificial limb. Particularly is this true of cases in which the knee can be saved, although the condition of some may be greatly improved by a thigh-amputation. Among those in which the knee can be saved will be found a few cases of old infantile paralysis (talipes), and adult cases of congenital talipes, in which painful bursæ have developed, and life rendered unendurable from the pain caused by walking.

On the other hand, old subluxated knees, with ankylosed patellæ, flail-joints and great shortening, are not uncommon. I have known several of these cases that were converted from hopeless cripples into useful members of society by a proper amputation and the adjustment of an artificial limb.

The orthopædist is very frequently called upon to improve the condition resulting from the recognized, though barbarous, amputations through the tarsus, the only remedy for which is an amputation above the ankle-joint and an artificial limb.

The reason for these suggestions will be very apparent after an inspection of a modern artificial limb.

I will briefly report a few cases illustrative of the good done by amputation performed orthopædically.

CASE I.—A. E., aged twenty-one years, single, called on me for advice in regard to an extreme deformity of the feet. He was very tall and thin, and gave me the following history: His family was phthisical. His feet were perfect up to eight years of age, when they gradually began to turn outward. He can give no explanation of this except that a tendency toward the position was produced by a pair of boots which were too short for him, and turned over at the heels, thus putting the structures on the inner side of the ankle-joint on a strain. There was neither paralysis, nor disease of the bones. Efforts had been made to arrest the progress of the deformity, but they were of no avail.[1]

The patient was six feet and four inches high, as he stood on the ends of the tibiæ, and I estimated that at least four inches were lost by the deformity. There was ugly ulceration of the parts which were pressed upon in walking. I advised for his relief a double amputation below the knees, and the application of two artificial limbs.

Both of the amputations were done at the same time, May 28, 1887, by the method of antero-posterior flaps with circular incision of the muscles. There was no mishap during his convalescence, and July 20th, just seven weeks after the amputations, he walked out of the manufacturer's shop on two Bligh legs, assisted with only a stick, the first patient in the experience of the maker who had ever done this, even when only one artificial limb was required. The patient has gradually improved in walking, and when I last saw him, a year ago, he told me he had walked four and a half miles in an hour and twenty minutes, on a country road.

The method by which this man walked on his deformed feet being similar to that employed while walking on artificial limbs enabled him to manage the latter with greater ease than is usual. In adjusting the artificial limbs his height was reduced to five feet eleven and one-half inches.

After his convalescence he became a theological

[1] Read before the American Orthopædic Association, Philadelphia, September, 1890.

[1] Casts of the feet were shown to the members of the Association.

student at Hanover, Indiana, and now has charge of a church in Southern California.

Case II.—W. M., aged sixteen years, the subject of chronic hip-disease, with recent pathological dislocation.

After a subperiosteal excision of the upper end of the femur it was discovered that the whole of the femoral shaft was the subject of osteomyelitis. Amputation was done forty-eight hours subsequently by the following method: The bone having already been removed, subperiosteally, sufficiently far down to allow the application of the Esmarch bandage so that the tourniquet would come above the bone, the amputation was proceeded with by the mixed method—skin flaps antero-posteriorly, and circular incision of the muscles. No sawing of the bone was required, as the circular division of the muscles corresponded with the upper end of the bone so nearly that the limb slipped away without any difficulty. The boy gradually recovered, and reproduction of bone occurred in the stump, the whole of the periosteum being left in a tolerably fair condition.

This amputation, necessitated by force of circumstances, suggests this method as a practical one in all cases where disarticulation at the hip is necessary, as it permits the application of the Esmarch bandage and a bloodless operation. When the case was last examined two years and a half had passed since the amputation. Bone had been reproduced down to the end of the periosteum, and the joint was controlled by the muscles as if the original bone had never been removed. He uses an artificial limb, and I have seen him walk on rough roads with no more difficulty than is ordinarily exhibited by a patient when first trying to use an artificial limb.

Case III.—Miss M. T., aged eighteen years, had an inflammation of the left knee at the age of three years. Upon examination there were found five inches of actual shortening, and great atrophy of the limb. The shortening was due to subluxation of the tibia and arrested development. She was unable to use the limb without the aid of a long splint extending to the hip and perineum, besides a five-inch patten. By the aid of these she could get about with great difficulty, and suffered from many painful exacerbations of the inflammation, due to falls.

Amputation above the knee was advised, and was performed, July 17, 1884. Within three months she had a Bligh leg adjusted, and since then she has been able to walk with comparative ease, and in comeliness and comfort is greatly improved.

Case IV.—C. W., aged twenty-four years, single, gave the following history: When about six years of age he received a blow upon the right knee, which was followed by acute inflammation of the joint, the limb rapidly becoming flexed. Various surgeons treated him, and many attempts were made to straighten and keep straight the limb. In the course of time an abscess occurred, from which pieces of bone removed. For the last ten years or more he had walked by the aid of a crutch with a stirrup upon it.

On examining the patient I found his limb flexed to an angle of about ninety degrees, perfect bony ankylosis having taken place. It was much atrophied, although the muscles between the pelvis and thigh were well developed. The femur was bowed anteriorly from the weight thrown upon it while walking, the leg below acting as a lever.

The patient wanted his limb straightened, and after discussing the various procedures to bring about this result, we decided on the removal of a wedge-shaped piece of bone, including in the wedge the patella and part of the condyles of the femur and tibia—Buck's modification of Barton's operation.

On September 27, 1882, the operation was performed, the limb being straightened by force until the bony surfaces were in apposition. In order to accomplish this it was necessary to divide both hamstrings.

He took chloroform badly, which required the operation to be performed very rapidly, but no untoward symptoms followed after he was put to bed.

The patient was able to be about on crutches at the end of three weeks. In five weeks all dressings were removed, and the union was found to be bony. The external wound also had healed. There were two and three-fourths inches actual shortening.

This patient, in the eight years that have passed since the operation, has had no trouble, and walks well without a cane or crutch.

When this result was accomplished I felt that I had done a creditable piece of surgery; but in the light of subsequent experience I now feel that in consideration of the greater danger of excision, and of the stiff knee and high shoe, that I would have done this man a greater service by amputating above the knee. Other cases might be instanced, but these are sufficient to illustrate the fact that amputation is often an orthopædic measure.

218 W. Chestnut Street.

VERATRUM VIRIDE IN PNEUMONIA.

By WILLIAM MARTIN, M.D.,
of Bristol, Pa.

In the present age of scientific medicine the opinions of medical men differ as to the most rational and safe method of treatment of nearly all affections, and especially in the treatment of pneumonia do the views of physicians diverge widely.

In all the diseases which are acute in character and in which the crisis is reached in a few days, prompt medication is important, and without this promptness valuable lives may be lost. Some practitioners have no distinct plan of treatment in pneumonia, but rely on being able to combat symptoms as they arise; thus the disease often gets beyond control.

The principal difference of opinion in the treatment of pneumonia is with reference to venesection, and the use of the so-called arterial sedatives. The old method of treating acute inflammations of deep structures by venesection is revived, and has its

advocates, who announce great results and defy the profession to show equally good results by any other mode of treatment.

The majority, however, still practise the more recent method, that by the administration of remedies which have a sedative action on the circulatory system, of which the most valuable though not the most used is veratrum viride.

This drug is not used by many physicians because it has the reputation of being dangerous, and some who have used it may not have had good results simply because it was either not properly administered or because the tincture was not pure and of standard strength. When pure the tincture of veratrum is very efficient, and in the author's experience better results have been obtained by its administration than by any other plan of treatment. The best form to use in this disease is the pure tincture (Norwood's).

The dose should at first be small, gradually increasing until the physiological effects are produced, when, if the toxic symptoms are marked, it should be discontinued, and need not be renewed, except in rare cases. When the toxic point is reached such symptoms as depression, nausea, and, possibly, vomiting may develop, but these quickly disappear.

Professor Bartholow[1] writes: "Notwithstanding the very formidable symptoms produced by large doses, fatal results have been extremely rare."

The principal effects of veratrum are reduction of the force and number of the heart-beats and lowered arterial tension. The drug may be carefully pushed so that the pulsations are reduced to but little more than thirty per minute without bad effects if the patient remains in the recumbent position. If depression, vomiting, and other symptoms appear, stimulation and a little morphine will soon produce reaction.

The best time to administer veratrum in pneumonia is in the first stage, but it is also beneficial in the second stage, the stage in which cases are usually first seen. The influence of the drug is similar to that of venesection, but is more precise, as the pulse can be reduced at will and at the same time lessened in force, thus reducing the blood-supply of the lungs, preventing further consolidation, and hastening resolution. In cases with feeble constitutions, such as inebriates, in which depression would be harmful, the results are better if the drug is not given in amounts sufficient to cause its physiological effects, and in these cases it is usually necessary to give ammonium carbonate with the veratrum.

It is very easy to find the proper amount for each patient if the drug is first given in small doses and increased gradually, for the effects will always be manifest before a lethal dose is given.

[1] Materia Medica and Therapeutics

In cases with high temperature, rapid pulse, and labored respiration, the effects are marvellous: the temperature falls usually to normal, sometimes to a degree below; the pulse is reduced, sometimes to one-fourth of the previous rate; and the respirations become deep and quiet; while the patient, if vomiting does not occur, quietly falls asleep and awakens refreshed and better—the crisis is over.

By this method of treatment cases seen early may be aborted, and convalescence may be hastened in those seen in the second stage. Such local measures as may be indicated, should, of course, be used in combination with this internal treatment.

In a number of cases treated in this manner by the author, the average duration of the disease was remarkably short, especially in view of the fact that four were cases of double pneumonia and that one was phthisical.

Summarizing, we find that:

1. The administration of veratrum viride is the preferable method of treating pneumonia, and that the drug is best given in the form of a tincture, (Norwood's).

2. If the dose is at first small and gradually increased it is a safe medicament.

3. It should be given early, and if possible, in the first stage, though it is also of use in the second stage.

4. If used in cases with broken-down constitutions, as in inebriates, it should be administered cautiously. In such cases there is immediate danger from the depression, and the toxic effects should not be produced.

CLINICAL MEMORANDA.

THERAPEUTICAL.

Aristol.—The efficacy of the dry treatment by means of absorbent powders has been so frequently and positively manifested in cases of superficial wounds and ulcerations, that any substance which combines the qualities of a rapid absorbent, of a mild stimulant, and of a powerful antiseptic, is most valuable to the surgeon.

Many drugs for which these qualities are claimed have been recommended, and of all iodoform has been most generally accepted by the profession. This substance has, however, certain positive disadvantages. Its odor is penetrating and lasting, and to many patients intolerable. If applied to large surfaces the danger of toxic symptoms developing from absorption has been proved by numberless recorded cases. Hence, substitutes for this material are constantly being brought forward. Hydronaphthol and iodol promised well, and yielded good results, but after a comparatively brief trial their use was discontinued.

The latest substitute for iodoform is aristol, a combination of thymol and iodine. Aristol is a fine, absorbing powder, without unpleasant odor, and it is said never

occasions toxic symptoms, nor causes undue irritation of a wound, being, moreover, a powerful antiseptic.

Bacteriological researches have not proved the antiseptic power of aristol. This, of course, does not conclusively settle the matter from a medical point of view, since iodoform is in the laboratory absolutely destitute of germicidal properties, though few doubt its efficacy in cases of suppurating wounds.

With a view to determining the applicability of aristol to the ordinary surgical affections encountered in dispensary practice, for it is here that the drug, if well approved, will mainly be of use, I directed one of my students, Mr. R. Pittfield, to record carefully the results of its employment as a dusting-powder in a comparatively large number of selected cases. It is difficult to tabulate accurately the results obtained in these cases, and no just judgment can be formed of the drug until its use is much more widespread than at present. In general terms it may be stated that the observed effects were very similar to those noted after the employment of iodoform. The wounds and open surfaces remained dry, granulations were slightly stimulated, and healing progressed favorably. Good effects were particularly marked in several cases of ulcerating gummata. In these there was pronounced improvement immediately upon substituting aristol for iodoform.

In but two cases was there any ill effect from the powder. In these granulations, which previously had been comparatively healthy, became highly inflamed and slightly sloughing, so that iodoform had to be used.

As a result of the application of aristol to a variety of cases it would seem that the drug may be fairly ranked with iodol, hydronaphthol, and iodoform in so far as its immediate effects are concerned, that it is particularly serviceable in cases of ulcerative syphilis, and that it possesses the advantage of being devoid of disagreeable odor. As to whether it can by decomposing in foul wounds render septic products innocuous is yet to be determined, and upon this point will depend either its universal use or its relegation to the obscure position occupied by so many drugs which have been advocated from time to time.

Edward Martin, M.D.,
Assistant Surgeon to the
Hospital of the University of Pennsylvania.

OBSTETRICAL.

Veratrum in Eclampsia.—The following case did not differ materially from the majority of cases of eclampsia, and it is chiefly to the treatment that I desire to call attention.

On May 22d, early in the morning, I was called to see Mary S., a robust negress about twenty years of age; primipara. She was unconscious, and both tonic and clonic convulsions were rapidly recurring. From her mother I learned that labor began on the previous evening, at which time the patient had a "fit," and that since then she had been unconscious. Several convulsions occurred during the night. As the least irritation would excite a convulsion, I gave half a grain of morphine hypodermically before making a vaginal examination. However, the morphine did not prevent a convulsion when I attempted to make the examination, so that I abandoned the idea of precipitating labor. The pulse was full and bounding, respiration labored and shallow, face and feet much swollen, and the kidneys not acting. Clonic convulsions became less frequent, but the condition of the respiration, skin, and pulse remained unchanged.

Although the symptoms indicated venesection, I was convinced that better results could be obtained from veratrum viride, of which I gave twelve minims of the tincture hypodermically, about two hours after the administration of the morphine. In a short time the pulse was reduced in frequency and became soft and compressible, the skin moist, and breathing less labored. I was told by the mother that the patient had answered twice when spoken to. The condition of the kidneys remained unchanged.

May 23. Condition was unchanged, except that a vaginal examination was made, which caused only twitchings of the muscles of theface and arms. Labor was advancing very slowly.

24th. The pulse increased in frequency and diminished in volume, and the skin became dry. I kept the patient quiet and gave morphine in small doses hypodermically. In the night the child was born. Hour-glass contraction followed, for which I gave chloroform, dilated the constriction, and removed the placenta. This operation caused convulsions.

The patient never regained consciousness, and died on the following afternoon. I was not present when she died, but from what the mother said I think that death occurred during a convulsion.

I am persuaded that veratrum is of greater utility than venesection, in cases where the symptoms seem to indicate the latter. Veratrum produces all the good effects of bleeding without the bad ones. It depresses, but does not exhaust the patient; it reduces the reflex excitability of the spinal cord, and it lessens very much, if it does not entirely check, the spasms. Pilocarpine should be used hypodermically, often enough to keep up free diaphoresis, and I believe that the fœtus should be removed as soon as it can be done without causing convulsions.

During the actual seizures, chloroform is our most potent remedy.

John H. Ayres, M D.
Accomack C. H., Virginia.

MEDICAL PROGRESS.

The Uses of Hydroxylamine.—Rosenthal (*Deutsche medicinische Wochenschrift*, No. 35, 1890) has thoroughly reviewed the recent work on the uses of hydroxylamine. Comparatively few practitioners have employed the drug in the treatment of disease, and its effects have been chiefly observed in the management of skin affections. Thus, Eichhoff has used the drug in some parasitic and bacillary diseases of the skin. He has treated five cases of lupus, five of herpes tonsurans, and one of sycosis with the following ointment:

R.—Chlorohydrate of hydroxylamine . . . 1½ grains.
Alcohol, Glycerin, of each . . 12½ drachms.—M.

This mixture may be employed five times daily, but the parts treated must be previously washed with soap and water. Owing to the irritant and toxic properties of the drug, the solutions when first used must not be very

strong. A case of lupus of the upper lip and nose yielded to this treatment in eight days, and at the end of four weeks the ulcers were entirely cicatrized. In the cases of herpes tonsurans the application of the drug was followed by eczema of the scalp, but the final results were good and were rapidly attained. Eichhoff thinks that good results may also be attained in psoriasis, parasitic and seborrhœic eczema, and in the eruptions of syphilis, and that subcutaneous injections may be employed in the treatment of leprosy.

Fabry observed twenty-four cases of psoriasis treated with hydroxylamine, and found that the action of the drug resembled that of chrysarobin and pyrogallic acid, with the advantage that it did not stain the clothing. Care, however, must be exercised in the employment of the drug, owing to its poisonous properties. Thus, the application of hydroxylamine in one patient, a woman, was followed by very marked albuminuria, which ceased with the suspension of the treatment. Fabry has employed the medicament associated with calcium carbonate, as follows:

℞.—Chlorohydrate of hydroxylamine . . . 3 to 4 grains.
Alcohol . . . . 15 drachms.
Carbonate of calcium, a sufficient quantity to neutralize. —M.

℞.—Chlorohydrate of hydroxylamine. . . . 15 grains.
Water . . . . 2 pints.
Carbonate of calcium, a sufficient quantity to neutralize. —M.

Blaschko advises an ointment of lanolin containing one or two per cent. of hydroxylamine. Such a preparation causes no pain and is well borne. Eichhoff has more recently employed a three-per-cent. ointment with success in one case of psoriasis, one of seborrhœic eczema, one of herpes tonsurans, and four of sycosis. Kantorowicz has also obtained good results with the employment of Eichhoff's formula. A case of herpes tonsurans was completely cured in twenty-four days.

Groddeck has employed hydroxylamine in the treatment of twenty-five cases, with variable success. In solutions of a strength of 1 to 1000 the drug produced irritation, and in many cases it did no good. On the whole, he found hydroxylamine inferior to chrysarobin and pyrogallic acid, and, owing to its toxic properties, he thinks its use should not be extensive.—*La Médecine Moderne*, September 18, 1890.

The Treatment of Diphtheria by Inoculations of Erysipelas.—Babtschinski observed three severe cases of diphtheria which resulted in recovery after the spontaneous appearance of erysipelas. This led him to experiment with the treatment of diphtheria by inoculations with the cultures of the erysipelas microbes. Fourteen patients were treated by this method. The inoculations were made by means of scarification in the neighborhood of the submaxillary lymphatic glands. The symptoms of erysipelas showed themselves in from four to twelve hours, and as the erysipelas progressed the diphtheritic membrane gradually disappeared from the fauces, the lymphatic engorgement diminished, and the temperature fell. In two cases only was the treatment unsuccessful, and in these, death occurred before the erysipelas developed. No additional treatment was used, and other cases of diphtheria occurring in the families of those inoculated were, without exception, fatal.—*London Medical Recorder*, September, 1890.

Tetanoid Convulsions probably Due to Infection of the Umbilicus.—Mr. T. R. Ronaldson (*Edinburgh Medical Journal*, October, 1890) reports an interesting case of tetanoid convulsions in an infant. When the infant was nine days old, winking of the left eye and twitching of the same side of the face appeared, and with these symptoms swelling of the tongue. The spasmodic symptoms increased, and on the third day of the attack Mr. Ronaldson was called to attend the child. At this time the infant's appearance was that of health, and the only symptoms were the convulsive attacks, which were confined to the left side, beginning as tonic and ending as clonic spasms. On examination, the stump of the cord was found still attached to the umbilicus, and, though dry, had a putrefactive odor. There were no signs of inflammation around it. The remains of the cord were removed by means of scissors, and the stump was washed with bichloride solution and dressed with zinc ointment. The attacks, however, continued in spite of the administration of potassium bromide, chloral, and chlorodyne, and the application of twenty-per-cent. solution of cocaine, and nitrate of silver. On the seventh day of the attack the seizures became general, and recurred 204 times in twenty-four hours. On the thirteenth day, although the stump was rapidly healing, the umbilicus was excised. The fits at once diminished in frequency. On the fourth day after operation there were no seizures, but on the following evening they returned. The silkworm-gut sutures were then removed, after which the attacks diminished in frequency, although they did not disappear. Eight days later, sulphocarbolate of sodium, four grains every two hours, was prescribed, with the result that the digestion was upset and the fits became more frequent. Reducing the dose of sulphocarbolate, the convulsions gradually became less frequent, and none occurred after the thirtieth day following the operation. The child has since then remained in good health.

The excised umbilicus was examined by Dr. Edington, but no microörganisms were found.

Powder for Migraine.—The following powder is recommended in *La Médecine Moderne* for the treatment of migraine:

℞.—Citrate of caffeine . . 1½ grain.
Phenacetin . . . 2 grains.
Sugar of milk . . . 4 " —M.

To be made into one powder. This dose may be repeated, if necessary, in the course of two hours.

Treatment of Gastric Ulcer.—In the *Revue Général de Clinique et de Thérapeutique*, the following summary of the treatment of gastric ulcer is given by Eloy. In cases where absolute intolerance of milk exists, predigested foods are to be employed, and the milk should be peptonized. Beyond the diet, four indications are to be combated—namely, gastralgia, flatulence, vomiting, and hæmorrhage from the stomach. For the pain in the belly it is recommended that the patient shall receive

an injection of morphine and a hot application or a mustard-plaster to the epigastrium; while if pain is due to the ingestion of food, we can resort to preventive measures only, which consist in the employment of liquid and unirritating foods, and the administration of five drops of the following mixture in a teaspoonful of water:

℞.—Hydrochlorate of morphine 2½ grains.
Cherry-laurel water . . ½ drachm.—M.

If constipation exists with the gastralgia, small doses of belladonna may be employed, or, as has been recommended by Bartholow, a powder consisting of 2 grains of subnitrate of bismuth and ¼ of a grain of sulphate of morphine, may be taken shortly before the meals. In some cases, however, small quantities of atropine may with advantage be substituted for the morphine. The following prescription may be found of service:

℞.—Atropine . . . . $\frac{1}{10}$ grain.
Subnitrate of bismuth . 1 drachm.—M.

Divide into ten powders, and take one at night and in the morning. If the vomiting is obstinate, small pieces of cracked ice may be held in the mouth and cold may be applied to the epigastric region by means of the ice-bag, while warmth is applied to the feet. Under these circumstances, too, subnitrate of bismuth is valuable. For the flatulence which is so commonly present in these cases, it is recommended that small amounts of calcined magnesia be ingested, or that a very small cup of coffee be taken three times a day. For hæmorrhage from the stomach the physician should administer ice, tannic acid, acetate of lead, and antipyrine. The acetate of lead, when prescribed, should be combined with morphine, but when tannin is used it is best associated with opium, as is shown in the following prescriptions:

℞.—Acetate of lead . . . 3 grains.
Hydrochlorate of morphine 1 grain.
Powdered white sugar . 1 drachm.—M.

Make into ten powders, and give two to five a day, or one every hour.

℞.—Opium and tannin, of each 10 grains.
Pure opium . . . 3 "
Powdered sugar . . . 1½ drachms.—M.

This is to be divided into ten powders, and one powder is to be taken every one or two hours, or oftener, if necessary.

Antipyrine is often employed in hæmatemesis, because of the hæmostatic effect which has been noticed by Henocque, Huchard, and Arduin. It may be administered in powders of ten grains, one every hour for five hours, associated with cocaine. It is sometimes of great service when used as follows:

℞.—Hydrochlorate of cocaine 1½ grains.
Antipyrine . . . . 45 grains.—M.

Divide into five powders, and follow the administration of each by a tablespoonful of rum, as the alcohol favors the action of the antipyrine.

Tellurate of Potassium in Night-sweats.—According to *La Médecine Moderne*, October 21, 1890, tellurate of potassium has been found by NEUSSER to be valuable in the suppression and diminution of night-sweats. He employs one-third of a grain, in pill-form.

After the patients have taken this dose for a short time, it may be doubled without unfavorable results and with a good effect in reducing the quantity of sweat, provided the first dose has not been sufficient to control it. In rare cases the drug may produce dyspeptic symptoms. As a general rule, however, it has a favorable effect.

Local Anæsthesia for Slight Operations.—For operations upon small abscesses, opening fistulous tracts, or removing superficial growths, it is recommended that local anæsthesia be secured by atomization of the following solution:

℞.—Chloroform . . . 10 parts.
Sulphuric ether . . . 15 "
Menthol . . . . 1 part.—M.

The anæsthesia which is thus obtained lasts from two to ten minutes.

Mixture for the Treatment of Smallpox.—According to *La Semaine Médicale*, the following is a useful mixture for the treatment of variola:

℞.—Sublimed and washed sulphur . 2½ drachms.
Glycerin, Water of orange flowers } of each 6 "
Simple syrup . . . . 5 "

Mix, and give a coffeespoonful to children, or a tablespoonful to an adult, every two or three hours.

The Action of Hypnal.—This drug, which is variously known as monochloralantipyrin or monotrichloracetyl dimethylphenylpyrazalon, has been recently introduced by certain European physicians as a valuable hypnotic and analgesic.

In the *Bulletin Générale de Thérapeutique*, September 30, 1890, FRÄNKEL has presented an exhaustive study, not only of the chemical constitution of hypnal, but also of its physiological action and the best modes for its administration. The conclusions reached by Dr. Fränkel are that the drug is useful in the insomnia produced by excessive pain, and not only in the sleeplessness which results from cough arising from bronchitis, but also in that due to tubercular disease, and in neuralgic insomnia. It possesses all the properties of both chloral and antipyrin, or, in other words, both relieves pain and produces sleep. The very nature of the compound almost of necessity makes it a useful remedy, since, as is known to most of the profession, chloral in ordinary doses has little effect upon pain, and antipyrin, while relieving pain, rarely produces sleep.

Hypnal being quite insoluble in cold water, the best way to administer it is in some mucilaginous mixture which will hold it in suspension, such as syrup of acacia: the following formula is given by BARDET for its administration:

℞.—Hypnal . . . . 30 grains.
Syrup of acacia . . . 1 fluidounce.—M.

Dose: A dessertspoonful.

Or a very excellent formula is as follows:

℞.—Hypnal . . . . 15 grains.
Chartreuse . . . . 1 drachm.
Water . . . . ½ ounce.—M.

The entire amount to be taken in one dose, or to be divided into several doses when given to children.

SATURDAY, NOVEMBER 1, 1890.

AN UNJUST PROSECUTION.

THE readers of the daily papers in and about Philadelphia who are at all interested in medicine or pharmacy noticed several weeks ago that two of the leading druggists of Atlantic City had been arrested and charged with the misdemeanor of selling adulterated drugs.

A complete explanation of the arrest lies in the fact that the State of New Jersey some time ago adopted the United States Pharmacopœia as its standard of drugs. This action is laudable so far as it goes, and we think it would be fortunate if the remaining States of the Union would stamp officially the product of the Committee of the Revision of the Pharmacopœia with their approval. That an act done with the best intentions may, however, result in legal absurdities, is represented by the case before us. The druggists, who were fined fifty dollars each, were in the habit of preparing their tincture of nux vomica from the so-called normal liquid of Parke, Davis & Co., which is an assayed fluid, the strength of which is governed not by the quantity of solid extract, as is directed in the U. S. Pharmacopœia, but by the amount of active principle or alkaloid which the drug contains.

The Dairy Commissioner of New Jersey having obtained samples of nux vomica, had it analyzed according to the directions given in the last Pharmacopœia, with the natural result that the extract was not present in proper quantity, and upon the chemist's testimony the Justice before whom the druggists were taken at once administered punishment. That this punishment was unjust is, of course, at once evident to anyone who is familiar with the subject, and we would call attention to the fact that the authorities of the State of New Jersey could practically prosecute almost every druggist in that commonwealth for some similar breach of the letter of the law.

The advances which medicine and pharmacy have made in the last ten years practically prohibit the use of many impure substances, which owing to our lack of knowledge in 1880 seemed as pure as possible. Chief among these may be named saccharated pepsin, which everyone now knows is practically useless as compared to the pure pepsins which are manufactured by the leading firms in this country.

The ludicrous condition of affairs exists that for once honesty was not the best policy; for if the druggists who suffered had dispensed the officinal tincture of nux vomica the patients receiving the medicine would have received a more impure preparation than if the law had not been obeyed.

We earnestly hope that Governor Abbett will use his influence to have the present law either repealed or so amended that similar travesties on justice may not recur.

DR. BARTHOLOW'S RETIREMENT.

IN another column will be found the news of the retirement of Dr. Roberts Bartholow from the Chair of Therapeutics and Materia Medica in the Jefferson Medical College, and those who are interested in Philadelphia as a medical centre and in medical education throughout the country will hear with regret of the withdrawal of this eminent and brilliant teacher from the corps of active professors in this well-known school. Dr. Bartholow has always been one of the foremost in teaching the best and most advanced yet conservative employment of remedies for the cure of disease, and his precepts as enunciated in his works and lectures, have no doubt given encouragement and success to a large body of the profession, particularly in its younger element.

Dr. Bartholow having left a most lucrative practice in Cincinnati, was able to obtain in Philadel-

phia a foothold immediately upon his arrival, which his sterling worth strengthened from year to year, until its dimensions increased so greatly that he was forced to limit himself to consultations. We are assured that no one appreciates Dr. Bartholow's worth more than the trustees of the Jefferson College, and that his retirement was only decided upon after the most careful consideration.

A NEW JOURNAL OF NERVOUS DISEASE.

We welcome to our exchange list *The Review of Insanity and Nervous Disease*, which is a quarterly compendium of the current literature of neurology and psychiatry, edited by Dr. James H. McBride, of Milwaukee, Wisconsin, who has associated with him as collaborators Dr. Gray, of New York, Dr. Mills, of Philadelphia, Dr. Riggs, of St. Paul, Dr. Jones, of Minneapolis, and Dr. Bannister, of Kankakee.

After a careful examination of the pages of the first number we are forced to conclude that this is a publication which by reason of its able selection of abstracts is one to which every one who is interested in nervous diseases must subscribe, while the contents of this number are so uniformly good that the following issues will probably be equally worthy of praise.

SOCIETY PROCEEDINGS.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

Sixteenth Annual Meeting,
held in Louisville, Kentucky, October 8, 9, and 10, 1890.

First Day.—Morning Session.

The Association met in Liederkranz Hall, and was called to order by the President, Dr. J. M. Mathews, of Louisville, at 10 A.M.

Dr. Frank Woodbury, of Philadelphia, read the first paper, which was entitled

INFECTIOUS DYSPEPSIA AND ITS RATIONAL TREATMENT BY THE ANTISEPTIC METHOD.

Dr. Woodbury said that in the present unsettled condition of medical nomenclature dyspepsia is as much entitled to recognition as a distinct disease as is consumption or chorea. Like the latter diseases, it is characterized by manifestations of nervous disorder, so that Cullen was not entirely wrong in considering dyspepsia as a neurosis belonging to the class of adynamiæ. Like pulmonary phthisis, its most marked symptoms are produced, the author believes, by the absorption of the products of parasitic microörganisms.

Abelous, a recent investigator of this subject, found sixteen species of microörganisms normally existing in his own stomach, of which two species were micrococci, thirteen bacilli, and one was a vibrio.

Habitually laborious, painful, and imperfect digestion, when not symptomatic of other disease, constitutes dyspepsia; and when accompanied by fermentation of the contents of the stomach and general toxic symptoms, the result of microbian development, it may properly be called infectious dyspepsia.

The disorder is sufficiently prevalent and gives rise to enough discomfort and actual suffering not only to deserve our serious consideration, but also to enlist our best therapeutic skill. The excessive growth of microorganisms during digestion is favored by slow movements of the stomach and by a deficient quantity or defective quality of the gastric juice. Acid dyspepsia, or sour stomach, may, rarely, be due to excessive secretion of hydrochloric acid, but is generally caused by lactic, acetic, or butyric fermentation, produced by the bacteria in the stomach. The object of treatment in infectious dyspepsia should be to prevent the excessive development of microörganisms during the digestion of food. This is attempted (1) by the use of articles of diet which are not in a fermenting condition nor readily fermentable; (2) by adopting such hygienic and tonic measures as will invigorate the bodily powers, bring the gastric juice up to its normal standard of quality and quantity, and increase the muscular power of the stomach; and (3) by local antiseptic treatment, including the administration of drugs which retard fermentation, and especially by lavage or irrigation of the stomach with weak disinfecting solutions, or simply recently boiled water.

Dr. John H. Hollister, of Chicago, then read a paper on

HELP AND HINDRANCE TO MEDICAL PROGRESS,

and was followed by Dr. I. N. Love, of St. Louis, who, in a paper upon

COFFEE,

said that after an experience of five or six years he favored taking a cup of strong, black coffee, without cream or sugar, preceded and followed by a glass of hot water, every morning before rising, or at least one hour before breakfast. The various secretions are stimulated, the nerve-force is aroused, and the day's labor is easier, no matter how the duties of the preceding day and night may have drawn upon the system. Another cup at four in the afternoon is sufficient to sustain the energies for many hours. In this way the full effect is secured. The ideal food for brain-workers is hot milk, and if this regimen be followed and accompanied with at least eight hours of sleep in every twenty-four hours, the capacity for work is almost unlimited.

Dr. George Hulbert, of St. Louis, Missouri, read an interesting paper on

MECHANICAL OBSTRUCTION IN DISEASES OF THE UTERUS,

and submitted the following conclusions:

1. Normally we find the uterus in form and structure endowed with a capacity for menstruation far in excess of the demand.

2. In the pathological conditions considered as essen-

tial for mechanical obstruction we find that the conservation of force regulates the conditions so effectually that the capacity for menstruation is not abolished, and that the function is accomplished, unless there is *atresia*.

3. The phenomena believed to be dependent upon mechanical obstruction are not due to the forcible expulsion of retained fluids through the uterine canal, but are produced within the tissues, and are due to a disturbed rhythm of physiological forces caused by abnormal inervation, muscular action, and circulation.

4. The correct and rational interpretation of the testimony offered by symptomatology, pathology, and therapeutics removes mechanical obstruction from the domain of gynecology as a demonstrable fact, save in *atresia uteri*.

AFTERNOON SESSION.

The Association was called to order at 3 P.M. by First Vice-President Dr. C. R. Earley, of Ridgway, Pa.

DR. R. STANSBURY SUTTON, of Pittsburg, Pa., made (by invitation) some remarks on

THE SURGICAL TREATMENT OF UTERINE FIBROIDS,

and exhibited specimens.

DR. WILLIAM PORTER, of St. Louis, Mo., contributed a paper on

THE SELF-LIMITATION OF PHTHISIS,

in which he said that some time before his death Professor Flint promulgated the doctrine of the self-limitation of phthisis, and that this very interesting proposition was at one time freely discussed in various medical societies.

Dr. Porter said that after having carefully examined the facts cited in support of the proposition, he had no hesitation in asserting that there is not sufficient evidence to warrant us to accept the statement that phthisis is self-limiting, or that the element of self-limitation has a decided influence upon the result in any given case. He did not mean that all cases of phthisis necessarily die from the disease, but that when phthisis is firmly established there is nothing in the nature of the disease itself that indicates in any stage a fixed boundary—a line of demarcation as it were—but rather that all of its tendencies are progressive and downward.

DR. A. B. THRASHER, of Cincinnati, Ohio, then read a paper on

COUGH, ITS RELATION TO INTRA-NASAL DISEASE.

Cough, he said, is a reflex phenomenon due to the irritation of nerve-fibres in the bronchi, larynx, pharynx, nose, ear, stomach, etc.

A "normal" cough is for the purpose of freeing the air-tract from some foreign body. Irritation of the upper part of the trachea and of the ventricles of Morgagni most frequently produces cough, but irritation in many other locations may be referred by the sensory centres to this region, and thus give rise to cough. Inflammation of the cavernous bodies of the nose or of the septum has been known to cause a distressing cough that was mistaken for a symptom of tubercular disease. This is more apt to occur in persons of a neurotic temperament. The cough due to nasal disease may sometimes be recognized by its metallic ring and the absence of expectoration, and, as a rule, it can be provoked by touching the irritable spot in the nose with a probe. Dr. Thrasher cited the three following cases illustrative of nasal cough:

Case I.—In this case there were no subjective symptoms of nasal disease. The cough had been present for three months and was not benefited by the usual cough-mixtures. The lower turbinated body was hypertrophied, and touching it with a probe provoked violent coughing. The cautery was applied, and in three days the patient was well.

Case II.—A young woman who had been coughing violently for three months. She referred the irritation to the throat, which had been pencilled and sprayed for some time, with no relief. Touching the posterior extremities of either lower turbinated body produced violent cough. Treatment was adopted as in Case I., with good results in two months.

Case III.—Cough had been present for six months and was not benefited by constitutional or local treatment. The seat of the trouble was found to be in the left middle and right lower turbinated body. Treatment similar to that of the other cases was followed by cessation of cough within a month.

A paper entitled

THE THERAPEUTIC USES OF CARDIAC SEDATIVES IN INFLAMMATION,

by DR. H. A. HARE, of Philadelphia, was read by title in the absence of the author.

EVENING SESSION.

DR. JOHN A. WYETH, of New York, delivered the public address, taking for his subject

THE MEDICAL STUDENT.

Dr. Wyeth said that the first or preliminary stage of a medical student's education is his academic life, the second his medical college life, and the third his post-graduate or practical life, which extends from the day he leaves his alma mater until his usefulness ceases. Practical training may be acquired in three ways, as follows:

1. Service as interne, preferably for a term of two years, in a general hospital.

2. Service in some post-graduate college where all departments of practical medicine are taught by instructors especially trained in their respective branches.

3. Service as an assistant to one or more well-qualified practitioners in general medicine.

SECOND DAY.—MORNING SESSION.

DR. H. C. DALTON, of St. Louis, reported six cases of

PENETRATING STAB-WOUNDS OF THE ABDOMEN,

in which abdominal section was performed.

Case I.—A negro, aged sixteen years, admitted to the City Hospital, St. Louis, July 23, 1890. Patient had been stabbed two hours previously with a long-bladed knife. The wound was at the free extremity of the twelfth rib. Several inches of omentum protruded, but the general condition of the patient was excellent; pulse 62, respiration 23, temperature 100°. An incision was made in the left linea semilunaris. Blood and fæcal matter were found in the peritoneal cavity; there were two holes in the descending colon and one in the ileum, which were closed with continued iron-dyed silk sutures.

Discharged from the hospital, cured eleven days after admission.

Case II.—A man, aged twenty-one years, admitted August 21, 1890. He had received three stab-wounds an hour and a half before admission, one of which was an inch below the costal border and four inches to the left of the median line, and through this wound three inches of omentum protruded. The second wound was an inch above and two inches to the right of the umbilicus; and the third was in the seventh intercostal space in the right axillary line. A wound of the jejunum was closed by interrupted silk sutures. Four inches of the seventh rib were resected, the diaphragm was split for three inches, and a wound in the liver was closed by one catgut suture. The diaphragmatic and cutaneous wounds were closed by continuous catgut sutures. Patient's temperature arose to 102° on the second day, after which he rapidly recovered.

Dr. Dalton laid particular stress upon the importance of carefully inspecting such wounds to the bottom, and severely condemned the method of trusting to the introduction of the finger.

He did not think that implicit confidence should be placed in Senn's hydrogen-gas test.

Dr. M. T. Scott, of Lexington, Kentucky, reported a case of

GUNSHOT WOUND OF THE INTESTINE,

in which four perforations were made by a large bullet. Complete recovery followed abdominal section.

Dr. J. B. Murdoch, of Pittsburg, Pa., contributed a paper on

TORSION OF ARTERIES AS A MEANS OF ARRESTING HÆMORRHAGE.

There are two methods, he said, by which torsion may be applied: (1) limited torsion, and (2) free torsion. In the first method, two pairs of forceps are required. One pair grasps the vessel at its cut extremity, and pulls it from the sheath. The artery is then seized by the second pair of forceps at a point from one-half an inch to an inch above the cut extremity, the second forceps being held at right angles to the long axis of the vessel. The first pair is then given three or four sharp turns.

By the second method only one pair of forceps is required. It is the method recommended by Bryant as not being likely to injure the external coat of the artery.

The following is a table showing the number of arteries, divided in cases of amputation, in which torsion by the second method was resorted to at the Western Pennsylvania Hospital for the arrest of hæmorrhage:

Femoral	116 times.
Popliteal	18 "
Axillary	18 "
Anterior tibial	317 "
Brachial	81 "
Radial	45 "
Ulnar	45 "

Dr. Murdoch said, in conclusion, that the advantages of torsion as compared with ligation are: (1) The greater facility with which it can be applied. (2) Torsion is a safer method, being less liable to be followed by secondary hæmorrhage. (3) Healing is facilitated, because the wound is free from any irritating or foreign body.

Dr. G. Frank Lydston, of Chicago, then exhibited the skulls of a number of the most notorious criminals of the world, and made some very instructive remarks with reference to their peculiarities, shape, size, etc.

AFTERNOON SESSION.

Dr. W. P. King, of Kansas City, Mo., contributed a paper entitled

WIRING THE SEPARATED SYMPHYSIS PUBIS, SUPPLEMENTED BY A PELVIC CLAMP,

which will appear in full in The Medical News.

Dr. C. H. Hughes, of St. Louis, Mo., read a very elaborate and profound paper, entitled

PSYCHOPATHIC SEQUENCES OF HEREDITARY ALCOHOLIC ENTAILMENT,

which was followed by a paper on

UREA AND SEROUS MEMBRANES,

by Dr. C. S. Bond, of Richmond, Indiana.

Dr. Archibald Dixon, of Henderson, Ky., in a paper on

INGUINAL COLOTOMY,

said that the subject of colotomy, always one of interest, has, during the past decade, received much attention from the surgical world. As a measure to ward off imminent death, colotomy is demanded in all cases of obstruction in the colon, from whatever cause. For imperforate anus the operation holds a special position. It is intended to prevent impending death, but it may also be regarded as a cure for the disease. In many cases it is the first step in the process of cure. In a few words, it may be said that the indications to operate in any given disease depend, in the first place, on the chance which the patient has of getting well without operation; and, in the second place, upon the degree of probability that success will follow the operation. In cases of acute obstruction of the sigmoid flexure, or other part of the bowel, there is practically but one termination—death. No case of volvulus, whether of the large or small intestine, has as yet been known to recover under purely medicinal treatment. Here, then, the indication is as clear as the indication in hæmorrhage from the carotid —operation.

Dr. Emory Lanphear, of Kansas City, Mo., read a paper on

HYPNOTISM IN ITS RELATION TO SURGERY.

He reported a case of double talipes in which the subject had chronic Bright's disease which contraindicated the use of ether, and also had valvular disease, which prevented the safe use of chloroform. Dr. Lanphear hypnotized the patient, and operated at the first *séance*, contrary to the generally accepted idea that at the first *séance* a sufficient degree of anæsthesia cannot be produced.

Another case (reported by the permission of Dr. Shaw, of St. Louis) was that of a patient suffering from Jacksonian epilepsy due to a brain-tumor. He was hypnotized and trephined, the dura was opened, and a tumor weigh-

ing one and one-half ounces removed. The bone was replaced and the operation, lasting an hour, was completed.

DR. HAROLD N. MOYER, of Chicago, then read a paper on

THE HYPODERMIC USE OF ARSENIC.

He said that the hypodermic use of Fowler's solution has been recommended by various writers, among others, Hammond, who claimed that the dose which can be administered in this way is much greater than that which can safely be given by the mouth. Hammond has given as much as fifty drops of Fowler's solution as an initial dose. Again, he has often given the drug by the mouth until the eyes were puffed and vomiting was almost incessant, and then continued the arsenic in larger doses by hypodermic injection, with cessation of all gastric symptoms and the cure of the disorder.

In the case of a girl fourteen years old, suffering from chorea, the patient was placed upon the hypodermic use of arsenious acid, beginning with 3 minims of a five-per-cent. solution, and increasing every second day until three weeks after beginning the treatment, when she was receiving 13 minims at each injection, equivalent to about 36 minims of Fowler's solution. At the ninth injection she was discharged cured.

In the case of a woman who presented herself at the clinic in Rush Medical College with an enormous lymphadenoma of the side of the neck, after a few deep injections into the glandular mass the tumor began to diminish rapidly. When it had decreased one-half, the patient ceased attending and further observations could not be made.

Dr. Moyer's observations are in accord with those of numerous writers who have reported good results from the use of Fowler's solution in various forms of glandular enlargement, such as lymphoma, lymphadenoma, and Hodgkin's disease.

THIRD DAY.—MORNING SESSION.

DR. H. O. WALKER, of Detroit, read a paper on

PERINEAL CYSTOTOMY VERSUS SUPRAPUBIC CYSTOTOMY.

He said that in choosing an operation we should be governed (1) by its safety, (2) by its simplicity, and (3) by its applicability to the majority of cases.

For the removal of stone, litholapaxy undoubtedly stands preëminent, and can be done upon many patients past the age of three years, yet there are numerous restrictions to this method, such as stricture of the urethra, the large size of the stone, an enormous prostate, etc. There can be no question that when cutting has to be done the medio-bilateral method presents many advantages.

In looking up the literature of suprapubic operations since 1883, Dr. Walker found in the records of between three and four hundred operations, an average mortality of 30 per cent. A few operators have had a series of cases ranging from three to ten without a death. The most remarkable record in this respect is that of Dr. Hunter McGuire—twenty-one operations with but a single death. By the perineal method we find a mortality of from 5 to 9 per cent., rarely greater.

DR. EDWIN WALKER, of Evansville, Indiana, then reported

TWO CASES OF TUBAL PREGNANCY.

The first patient was twenty-seven years old, married for four years, and sterile. She had a history of uterine and tubal trouble before marriage. The menses were always irregular and were often missed for a month or two. She menstruated on June 29, 1890, but not in July. A few days after the missed period she began to suffer from severe pain in the right groin. On August 1st a sanguinous flow began, and an examination under ether revealed a soft tumor the size of a fist to the right of and behind the uterus. On August 17th the abdomen was opened, and the right tube, which was very large, was found ruptured. There was a large amount of clotted blood in the pelvis. The abdomen was irrigated with hot water and a glass drainage-tube used. The fœtus was not found. The operation was followed by some vomiting and pain, but recovery ensued without other bad symptoms. Drainage-tube removed on the third and sutures on the twelfth day. The highest temperature was 101.1°.

The author thinks that the present status of the question of operating is, that with such symptoms as were present in this case, abdominal section is the safest procedure to adopt.

DR. WILLIAM T. BELFIELD, of Chicago, in a paper entitled

A RÉSUMÉ OF EXPERIENCE IN THE VARIOUS OPERATIONS FOR CYSTITIS FROM PROSTATIC HYPERTROPHY,

reported 133 cases of operations upon the hypertrophied prostate, including eight of his own, as follows: Forty-one by perineal excision, mortality 9 per cent.; eighty-eight by suprapubic cystotomy, mortality 16 per cent.; four by combined perineal and suprapubic incision, none of which were fatal.

In fifty-six of these cases the patients had cystitis and had been dependent upon the catheter for periods varying from one to ten years. In all the cystitis was cured; in thirty-eight cases (two-thirds) the power of voluntary urination was restored and continued during the time of observation; in eighteen cases this function did not return.

Fifteen of the fifty-six cases were complicated with stone; excluding these, since it might be objected that the cure resulted from the extraction of the calculus rather than from the prostatic operation, there remain forty-one cases of uncomplicated prostatic operation. Of these, thirty-two (four-fifths) recovered the power of urination, and in nine this ability was not recovered.

DR. S. NORMAN, of Evansville, Ind., contributed a paper entitled

THE TREATMENT OF ORGANIC STRICTURE OF THE MALE URETHRA,

in which he said that in the practice of urethral surgery the operator cannot be too strongly impressed with the fact of the exquisite tenderness and sensitiveness of the urethra, and that the employment of the slightest amount of force in the introduction of an instrument should be regarded as a relic of barbaric surgery. When commencing the treatment by gradual dilatation, in sen-

sitive patients, Dr. Norman always produces local anæsthesia by the injection of from twenty to thirty minims of a four-per-cent. solution of hydrochlorate of cocaine.

Relative to internal urethrotomy, he believes that if it is properly and thoroughly executed and if special care is exercised to maintain the patency of the canal until the wound is healed, recontraction is of rare occurrence. Authority is divided in regard to the propriety of performing internal urethrotomy in the bulbous or in the membranous urethra. Judging from the results obtained by Harrison, the combination of external and internal urethrotomy offers encouragement for the permanent cure of stricture. Dr. Norman has performed external urethrotomy without a guide only three times, but the results as regards the absence of recontraction were entirely satisfactory. External urethrotomy with a guide is a simple operation, can be performed with facility and rapidity, and promises more satisfactory ultimate results than internal urethrotomy performed in the deep urethra.

Dr. L. S. McMurtry, of Louisville, then made some impromptu remarks on

THE APPLICATION OF ANTISEPTIC METHODS IN MIDWIFERY PRACTICE.

He said that many medical practitioners can remember the time when the wards of certain hospitals were closed and undergoing renovation because puerperal fever had become epidemic, whereas a hospital to-day is the safest place in which a woman can be confined. A few years ago we were taught by Fordyce Barker that puerperal fever was an entity, a distinct fever, dependent upon a specific *materies morbi*. To-day we know that puerperal fever, so-called, is a septic peritonitis. A woman after labor is a wounded woman. She has undergone certain physiological processes, and has received injuries in the process of labor which open the lymph-channels by which she may be infected from without. There is no such thing as a woman having peritonitis without external infection.

To prevent this infection the vagina must be sterilized, the bed, the examining finger, and the nurse must be surgically clean, and the atmosphere as approximately aseptic as it is possible to make it.

The following papers were also read: The Advantages of Attending Medical Societies and of Reading Medical Journals, by Dr. T. B. Greenley, of West Point, Ky.; Internal Urethrotomy, with cases, by Dr. J. V. Prewitt, of West Point, Ky.; Was It Relapsing Fever? by Dr. A. D. Barr, of Calamine Springs, Ark.; Some Remarks on the Prevention of Myopia, by Dr. Francis Dowling, of Cincinnati, Ohio.

OFFICERS FOR 1891.

President.—Dr. C. H. Hughes, of St. Louis.

First Vice-President.—Dr. John H. Hollister, of Chicago.

Second Vice-President.—Dr. S. S. Thorn, of Toledo.

Secretary.—Dr. E. S. McKee, of Cincinnati.

Place of meeting, St. Louis, Missouri, on the third Wednesday in October, 1891.

NEW YORK ACADEMY OF MEDICINE.

HYDROPHOBIA:

Abstract of a Discussion by the Neurological Section of the New York Academy of Medicine, October 16, 1890.

The President of the Section, Dr. Landon Carter Gray, in discussing the clinical aspects of hydrophobia, said that the extreme variability in the period of incubation has given ground for the belief held by many competent observers that if such a disease as hydrophobia really exists, death may also occur as the result of fear, with symptoms closely resembling the true disease. The speaker thought himself justified in assuming that frequent mistakes are made in the diagnosis of rabies, the so-called dumb rabies being merely a symptom of purulent meningitis and meningo-encephalitis, and that very few cases of either rabies or hydrophobia—the latter term being used to signify the disease in man—have been observed in New York City or in this country. He believes that there is a disease running a fatal course in the dog and other lower animals, and that it is capable of being communicated to the human being and causing death, though the evidence of this rests mainly upon pathological and experimental findings.

Dr. C. L. Dana said that there is no constant change to be found in this disease. The nerve-centres, which are the parts chiefly involved, are congested, and occasionally show hæmorrhagic and softened spots with subsequent evidences of increased vascular activity, exudation of leucocytes into the perivascular spaces, and, possibly, the beginning of a multiple focal myelo-encephalitis or of a focal necrosis. The symptoms are evidently not the result of organic changes in the nerve-tissues, but of a distinct poison—undoubtedly the product of microbic activity. In the light of Pasteur's scientific work this question of specific origin should be considered as proven. The speaker did not believe that there are authentic clinical records of a single case in which fear caused a disease similar to hydrophobia, or that there is a case of death from this hypothetical phantasm, although, possibly, tetanus or acute mania has followed bites in those predisposed by fright. He thought that Pasteur has demonstrated the fact that as a reliable prophylactic measure antirabic inoculations can be successfully employed.

Dr. H. M. Biggs then gave an elaborate description of the respective methods of inoculation and of the various emulsions used in the work both of Pasteur and Ferran.

Dr. H. C. Ernst, of Boston, said that he regarded the results of Pasteur as among the greatest achievements of modern medicine. The speaker was converted to a complete acceptance of the theory after conducting a series of inoculation experiments. Nothing in medicine, he said, is more certain than the results obtained by inoculating healthy rabbits under the dura with emulsions of the spinal cord of hydrophobic rabbits.

As to the existence of a lesion pathognomonic of rabies, he did not think that this could at present be defined with scientific accuracy, but careful observations have demonstrated the almost uniform presence of a white-cell infiltrate in the walls of the minute blood-

vessels in the medulla, engorgement of the veins, and occasionally peri-vascular hæmorrhages. What apparently are small miliary abscesses are also present. The condition has been aptly described by the term *miliary bulbitis*.

The speaker then gave the clinical histories of three cases of true rabies in man which had come under his personal observation, and which, taken with the fact that a large number of dogs were affected at or about the same period, pointed to the recent existence of an epidemic of rabies in Boston. One of the cases, cited in detail, was of special interest, because the patient between the paroxysms was able to describe his condition, and had been especially questioned as to whether he had any repugnance to water. This patient positively stated that he had no repugnance, but that any thought of deglutition caused an uncontrollable spasm of the muscles of the throat. The patient also said that he was perfectly conscious of his acts during the violent paroxysms, but utterly unable to control himself. Even while thus quietly describing his sensations a fit would come on, and the next moment he would be on the floor struggling with four or five men.

As to the value of preventive treatment, the speaker instanced the case of a boy who was bitten in August last by a dog which within fifteen minutes had also bitten several dogs, of which two died from rabies. The father of the boy becoming alarmed consulted the speaker. Inoculation was advised and submitted to twice a day, and no bad symptoms resulted. Before the boy's return home a third dog had succumbed to unquestionable rabies.

Whether there is anything in Pasteur's claims or not, one thing is certain: he has obtained a specific virus which can be transferred from one animal to another indefinitely, and always produces a sequence of practically identical symptoms. The experiments made by Dr. Spitzka were not carried far enough, although he produced in rabbits something similar to rabies.

While hardly wishing to be considered a champion of the Pasteur method if the statistics of the Institute were not reliable, Dr. Ernst said that he was still bound to believe in Pasteur's honesty of purpose. It is a significant fact that after the elimination of all cases in which an element of uncertainty exists, the mortality-rate for those treated by inoculation is only ninety-eight one-hundredths of one per cent. He expressed surprise at the statement that there could be no such condition as pseudo-hydrophobia or lyssophobia.

DR. R. W. BIRDSALL said that he had seen a number of cases of pseudo-rabies resulting from fright after a bite or scratch. These cases did not terminate in death, though he was not prepared to say that death from fright was impossible. The nervous shock received might set up a series of changes, such as motor paresis, œdema of the brain, and coma, resulting in death. He did not believe that we are yet able to refer the phenomena of true rabies to one variety of germ. The effects might be due to the presence of distinct varieties.

DR. H. P. LOOMIS said that he had considered the subject from a pathological standpoint only. His findings tallied very closely with those described by Dr. Ernst. Sections of the lower portion of the medulla showed congestion of the capillary vessels and giant-cell infiltration of the adventitia, but no capillary hæmorrhages or thrombi.

DR. BYRON, who has made extensive experiments both at the Carnegie and the Loomis laboratories, said that he had reached the conclusions that (1) inoculations of the specific virus of rabies under the skin are useless as a means of prevention, (2) that the results desired can never be produced by any process except subdural inoculation, and (3) that even then the effect is not inevitable. The question is a serious one and requires further research before any definite scientific conclusions can be formulated.

DR. E. C. SPITZKA said that he had made no experiments on rabbits, as intimated by Dr. Ernst, who had evidently not followed the points of the speaker's work. In the experiments made by himself on dogs by the introduction of various irritating substances into the brain, he had produced a bogus hydrophobia, but had never claimed that these were cases of true hydrophobia. He is now assisting in a series of elaborate experiments on rabies, the results of which cannot as yet be determined.

DR. L. C. GRAY, in closing, thought the discussion had proved (1) that there is among the lower animals a disease known as rabies, possibly constituting several diseases and due to different microörganisms; (2) that this disease is more frequent in the lower animals than is the similar disease in man known as hydrophobia; (3) that while this so-called rabies in animals occurs very often in this country, it occurs less frequently in the human being; (4) that very few medical men have seen cases of genuine hydrophobia; (5) that cases of pseudo-hydrophobia are by no means uncommon, and that death can result from the condition; and (6) that there is still considerable diversity of opinion as to the value of Pasteur's method, which should furnish material for discussion and incite to further experiment.

CORRESPONDENCE.

THE NERVE-SUPPLY OF THE SENSE OF TASTE

To the Editor of THE MEDICAL NEWS,

SIR: I have read Dr. John Ferguson's extremely interesting article in your issue of October 18th, and think that the author is to be congratulated upon having been able to observe so demonstrative a case.

But while this case seems to prove very definitely that the loss of taste in this instance was due to disease of the Vidian nerve, the evidence that the glosso-pharyngeal nerve is not concerned in supplying the sense of taste is very much weaker. In an article by myself on "Paralysis of the Trigeminus and Its Relations to the Sense of Taste (*Journal of Nervous and Mental Diseases*, February, 1886), I summed up the facts in support of the gustatory functions of the glosso-pharyngeal as follows:

"1. By anatomical dissections the fibres of this nerve have been traced directly to the taste organs (Vintschgau).

"2. By the Wallerian and atrophy methods, Vintschgau and Honigschmied have found that after resecting the glosso-pharyngeal nerves in young rabbits the peripheral portions and the taste-buds atrophy and disappear (Hermann's *Handb. der Phys.*).

"3. The physiological experiments of Magendie, Panizza, J. Reid, Broughton, Valentin, Wagner, Stannius, Lussana, and others, show that after resecting the glosso-pharyngeals the sense of taste is partly or wholly destroyed.

"4. The clinical evidence that the glosso-pharyngeal has something to do with the function of taste is almost unanimous. In all cases of trigeminal paralysis reported, so far as I can find, there is either no loss of taste or loss of taste only on the anterior two-thirds of the tongue, Gowers's cases being the only exceptions to this rule."

Dr. Ferguson's statement that paralysis of the trigeminus always causes complete hemiageusia is, I think, decidedly contradicted by facts. My own case (*loc. cit.*) may be cited as an instance.

In *Brain*, January, 1886, Dr. Thomas Harris reports a case in which a tumor involved the right side of the pons, entirely destroying the fifth nerve and Gasserian ganglion on that side, and causing total hemianæsthesia of the face and tongue, without loss of taste.

On the other hand, I have collected (*loc. cit.*) several cases of paralysis of the glosso-pharyngeal with loss of taste resulting.

I might add that Dr. Ferguson's report is incomplete in this, that he did not trace the degeneration of the Vidian back to Meckel's ganglion and the second branch of the trigeminus.

This does not, however, seriously affect the very convincing evidence, so far as it goes, which his case furnishes. But there have been other cases which almost entirely contradict this one, and which especially invalidate the theory that the glosso-pharyngeal has no gustatory function. Very respectfully,

Charles L. Dana, M.D.

50 W. Forty-sixth St., New York, October 22, 1890.

NEWS ITEMS.

Dr. Bartholow's Chair Vacated.—At a meeting of the Board of Trustees of the Jefferson Medical College held on Monday, October 27th, the Chair of Therapeutics and Materia Medica was declared vacant on the ground that Dr. Bartholow was mentally disqualified to hold the position. The most prominent candidates for the professorship are said to be Dr. S. O. L. Potter, of San Francisco, Dr. James C. Wilson, Dr. S. Solis-Cohen, Dr. Henry Morris, and Dr. T. J. Mays, of Philadelphia. The trustees adjourned after declaring the chair vacant, to meet on Monday, November 3d, to take further action.

Tri-State Medical Association.—The meeting of the Tri-State Medical Association of Mississippi, Arkansas, and Tennessee, has been postponed until November 19th and 20th.

The Saranac Lake Sanitarium for Consumptives.—Dr. J. Solis-Cohen informs us that he has received a letter from one of his patients in Dr. Trudeau's Sanitarium at Saranac Lake, reporting marked improvement in her own condition and in that of many other inmates. This patient was far from being a promising case, and the result speaks well for the system adopted by Dr. Trudeau. To quote from this letter: "So far, I have seen no place equal to the Sanitarium—not even the fine hotels. It should have been called 'Paradise for Consumptives.'"

A Caisson-disease Hospital.—The *British Medical Journal* quotes from an engineering periodical a description of a compressed-air chamber, or cylinder, for the reception of workers in tunnels and others who suffer from caisson-disease. Mr. Moir, the engineer in charge of the Hudson River tunnel work, has devised for his men, several of whom have been severely affected, a "hospital" for caisson-cases. This so-called hospital is a steel-plate cylinder, eighteen feet long by six feet in diameter, and is divided into two compartments, one of which is an air-lock. Both chambers have been fitted up with beds and everything necessary for the comfort of the patients. The air-pressure is maintained by a pump, so arranged that it will furnish a constant supply of fresh air. The degree of pressure is not kept very high, seldom, if ever, exceeding thirty pounds to the square inch. This degree of compression promptly retards the progress of the trouble, if the early symptoms receive attention.

Obituary.—Dr. Cosmo Brailly, formerly of New York City, died at Hazlett, N. J., on the 5th inst., aged seventy-six years. He was a native of France and a graduate of the University of Paris, but he had spent nearly fifty years of his professional life in New York.

Corrigendum.

CHLOROFORM AND THE HYDERABAD COMMISSION.

In the address of Dr. J. C. Reeve (The Medical News, October 18th) the third sentence should read: "The differences of opinion and practice which prevail as to the two great anæsthetics are far greater than ever prevail upon subjects fully and clearly understood."

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM OCTOBER 14 TO OCTOBER 27, 1890.

Jarvis, N. S., *Assistant Surgeon.*—Is granted leave of absence for one month, on surgeon's certificate of disability.—*S. O. 107, Department of Arizona.* October 14, 1890.

By direction of the Secretary of War, leave of absence for four months is granted James E. Pilcher, *Captain and Assistant Surgeon.*—Par. 12, *S. O 244, A. G. O.*, October 18, 1890.

By direction of the Acting Secretary of War, the retirement from active service, on October 12, 1890, by operation of law, of Andrew V. Cherbonnier, *Captain and Medical Storekeeper*, under the provisions of the Act of Congress approved June 30, 1882, is announced.—Par. 11, *S. O. 240, A. G. O., Washington, D. C.* October 13, 1890.

Glennan, J. D., *First Lieutenant and Assistant Surgeon.*—Is granted leave of abence for one month, to take effect about the 31st instant.—Par. 1. *S O. 146, Department of the Missouri.* October 23, 1890.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING OCTOBER 25, 1890.

Cordeiro, F. J. B., *Passed Assistant Surgeon.*—Detached from the U. S. S. "Nipsic," and granted three months' leave of absence.

Heffinger, A. C., *Passed Assistant Surgeon.*—Placed on the Retired List October 20, 1890.

ORIGINAL LECTURES.

PSOROSPERMOSIS FOLLICULARIS CUTIS.

A Clinical Lecture,
delivered at the New York Post-Graduate Medical School and Hospital, October 8, 1890.

BY L. DUNCAN BULKLEY, A.M., M.D.,
PROFESSOR OF DERMATOLOGY.

GENTLEMEN: The patient whom I present to you exhibits very clearly the characters of a somewhat rare disease which has recently attracted considerable attention, and the nature of which has given rise to no little study and discussion. I trust, however, that before I have finished you will recognize that the disease has more than a scientific interest; that our remarks of to-day will stimulate you to a further study of the general subject involved; and that some practical good may result therefrom.

The clinical history of the patient before us is as follows:

Mr. M. L., a German, aged forty-nine years, enjoyed good health up the time of his entering the U. S. army, in 1862, in which he served for three years. About a year after entering the service, without any apparent cause, except an immersion in a river, after which he was sick for some time, small, dark lesions appeared upon the forehead and over the sternum, similar to those now present; and from that time, twenty-six years ago, he has never been free from the eruption, which has gradually increased in extent. These lesions began as small, reddish-brown points, or papules, which gradually enlarged, and gave a rough feeling on passing the finger over them; where they were most numerous they coalesced to a greater or less extent, forming patches of a dirty yellowish-brown color.

The increase of the eruption has been gradual, but at times more rapid, especially in the spring and fall, when he has fever, with pains in the bones (which may be malarial) confining him to bed; at these times the affected portions become swollen and red, and, he states, have been mistaken for erysipelas. This latter statement is, of course, of no importance, for we all know how commonly unusual eruptions of a congestive character are called "erysipelas" by those unacquainted with skin diseases. He cannot tell the date at which the various portions of the body became affected, but remembers that the forearms and backs of the hands were attacked about fourteen years ago.

He has two daughters, aged respectively fourteen and seventeen years, also a son twenty-four years of age, all of whom are healthy and free from any eruption. He has lost one child aged six weeks. His father and mother never had any eruption, and he has a brother aged fifty-four years, and a sister aged fifty-seven years, living and healthy. Another brother died at the age of forty-three years of paralysis.

His present condition, as you see, is not very good. He has an anxious, careworn expression, and says that he is so nervous and weak that he cannot attend to any business. The skin lesions extend from the top of the head to the groins and upper thighs. The top of the head, which is bald, you will notice is almost covered with small, brown specks, filling the sebaceous orifices and giving a "nutmeg-grater" sensation on passing the finger over them. On the forehead the lesions are larger, varying from the size of the head of a small pin to that of a medium-sized flat bead; all are slightly raised above the surface, are either flat or rounded, and distinctly hard, though greasy; they are much the same on the cheeks, though here, as on other exposed parts, they are kept worn down by washing and friction. On the chest you see the disease most perfectly developed, and here, and on the abdomen, which is largely covered, the separate, hard, brown papules are more elevated, rougher, and of a darker color. On the back they are less thickly distributed, and on the forearms they are more closely set, forming patches. The groins and upper part of the thighs also exhibit thickly-developed masses of them, but nowhere do we find them so large or prominent as have been described in one or two similar cases; nor do we find a very distinct, fœtid odor which has been spoken of in other cases, although it is faintly marked here, and the patient says that at times it is much more perceptible.

The hands are rather peculiarly affected by the disease; on the backs there are single isolated papules, similar to those seen elsewhere, and also brownish, dirty patches, evidently made up of the papules, closely packed together. Notice also the nails, which are affected in a very remarkable manner. They are all greatly thickened, so as to be raised from their bed, and the thickening is in the centre, while the sides of some are atrophied, giving almost a claw-like appearance to them. All of them are, as you see, very fragile, both at the ends and sides, with furrows and fissures running longitudinally.

Observe, now, more closely the character of these papules, especially on the chest and arms, which appear at first sight to be firmly attached, and to form an integral part of the skin. They are quite easily raised with the point of a knife, without pain, and leave behind them a small depression, reddened, and somewhat resembling the surface left after picking out very small cups of favus; in some of them which I have thus dug out there is a little bleeding at the base. These small masses, then, seem to be rather loosely attached, and are evidently horny and fatty concretions seated in the orifices of the sebaceous glands opening into small hair-follicles. Some of these masses have already been examined under the microscope by my friend, Dr. Pol-

litzer, who reports the presence in them of the *psorosperms* which, according to the French observers to be referred to later, form the diagnostic feature, as they are the cause, of the disease. The wound on the head and one on the arm mark the sites where portions of the skin have been excised by us for further microscopical study, and you also see scars where portions have been removed by others on former occasions. I may here remark that this patient has been the subject of much observation and study by a number of physicians since I first treated him nearly ten years ago, and I may add that various opinions have been held as to the nature of his complaint. I am told that Dr. Lustgarten, of New York, first gave this patient's disease its present (and probably correct) name, and exhibited microscopical sections of the same at the recent Congress in Berlin.[1]

What, now, is this curious affection which has lasted for many years, and resisted varied and thorough treatment, even in hospitals? Although these cases are relatively rare, there are a number of them on record, and, as before remarked, the disease is worthy of study for many reasons.

At first sight this condition suggests an ichthyosis in which the lesions are separated and isolated, and we accordingly find that a similar condition was mentioned by Wilson[2] long ago, with the title *ichthyosis sebacea cornea*. Because of the evident implication of the sebaceous glands Guibout[3] afterward criticised Wilson, and, considering the condition as wholly inherent to the sebaceous glands, he gave it the name *acne sebacée cornée*. Next Lesser[4] considers the subject, and applies the name *ichthyosis follicularis* to the affection described by Guibout, and describes a case in a child, which he thinks is the same disease. Morrow[5] reports a case which is pretty certainly one of the affection under consideration, with the title *keratosis follicularis*, because he considered the nature of the affection to be a cornification of the products of the sebaceous glands and adjacent fine hair-follicles; still later White[6] reported a case of the same disease with the name *keratosis* (*ichthyosis*) *follicularis*, while Leloir and Vidal[7] very recently described it under the name *acné cornée*.

I have thus given you all that I know that bears on the subject previously to the studies of Darier[8] and Thibault,[9] which have turned our thoughts in quite another direction. These observers based their studies on two cases which appeared in the services of MM. Fournier and Besnier in the celebrated Hôpital St. Louis, of Paris. It is a little curious that just before they published their researches on the subject, one of these very cases was presented by M. Hallopeau,[10] one of the physicians of the Hôpital St. Louis, before the Society of the Hospital, under the name "*acné sebacée concrète* with hypertrophy."

In examining the plugs or masses forming the papules, Darier, who is the head of the laboratory at the Hôpital St. Louis, found that the cellular elements composing them did not all behave under staining reagents exactly like altered epithelial cells, and under the microscope he found that there were other bodies which were foreign to the tissues under consideration I cannot, of course, give you all the details of his elaborate microscopical study, but will only tell you that he found certain round or oval bodies situated within the epithelial cells of the lower layers, which he believed to be of parasitic nature. I will give you very briefly Darier's own condensed statement of the appearance of these bodies as he described them at the International Congress for Dermatology and Syphilography in Paris, last year:[1] "The malady is due to special parasites, which appear in the form of round, nucleated bodies, surrounded by a dense membrane, and situated in the interior of the epithelial cells whose nuclei they compress. They are found in great abundance at the bottom of the sac formed by the dilatation of the follicle: the horny plugs themselves are to a great extent composed of the parasites, but they are transformed in this situation into hard and refracting particles."

The number of cases thus far studied is too few to permit of very positive conclusions either in regard to the mode by which the disease is acquired, or as to the exact relation of these bodies to the production of the disease. I may say, however, that these same psorosperm-like bodies have been found by Dr. Bowen both in the sections originally taken from the first case observed by Dr. White, already referred to, and also in a second case which he has recently reported[2] under the title *keratosis folliculosis* (*psorospermose folliculaire végétante*), and, as already mentioned, in the plugs from the case now before you.

The exact nature of these bodies has not yet been fully determined. Darier believes them to be true parasites belonging to the order of sporozoaires, which are unicellular organisms belonging to the animal kingdom, and a subdivision of the protozoaires. This class includes (1) the gregarinæ, (2) the oval psorospermæ or coccidiæ (which is the one found in this disease), (3) the sarcosporidiæ, (4) the psorosperms of fishes or myxosporidiæ, and (5) the psorosperms of the articulates, or microsporidiæ. All these organisms live as parasites on other animals, and in certain cases give rise to fatal maladies. The coccidiæ, which alone interest us here, live almost exclusively in the epithelial tissues of vertebrates, where they are found even in the interior of the cells. They are distinguished from the other groups of sporozoaires, and especially from the gregarinæ, by several characteristics, such as the absence of movement at any period of their development, their intracellular location, their solitary encystment, and the relatively small number of spores formed in the cysts. The ovoid coccidia produce

cysts in the biliary ducts of the rabbit, and in the human liver and ureters[1] psorosperm cysts have been observed.

Before going further into the subject, and making what I hope will be practical suggestions, allow me very briefly to give the chief facts of the nine cases of this peculiar disease to which I have thus far found reference (including Dr. Morrow's and my own, and also three briefly alluded by Dr. Boeck, of Norway).[2]

1. (Fournier, Darier, Thibault.) Male, aged forty-two years, a bookbinder, affected for seven or eight years; the disease beginning at first insidiously, increased more rapidly during the last two years. The eruption was general.

2. (Besnier, Darier, Thibault.) Female, aged thirty years, affected for three years only, and presenting clinically the same aspect as the preceding.

3. (White.) Male, American, aged forty-nine years. Eruption first appeared beneath the knapsack, after a long march, when in the army in 1862, twenty-seven years before the date of observation.

4. (White.) Female, aged twenty-one years, in whom the eruption slowly developed after she was five or six years old.

5. (Morrow.) Male, aged twenty-one years, a sailor. Eruption appeared about five years previously to observation, soon after beginning a seafaring life.

6. (Bulkley.) Male, German, aged forty-nine years. Disease appeared when in the army, twenty-seven years ago.

7. (Boeck.) Male, aged forty-seven years, who had had the disease sixteen years; numerous encysted coccidia in epidermis.

8. (Boeck.) Male, son of former case.

9. (Boeck.) Male, also a son of case No. 7. From these cases in the same family Boeck argues for the contagiousness of the disease.

You will notice the singular fact that Dr. White's first patient and mine were at exactly the same age when first seen, and that both of them acquired the disease in the army. But Dr. White's patient was an American, and this man is plainly a German, and the ages are really different, as the former case was observed considerably over a year ago. Moreover, on careful inquiry our patient denies that he is the one referred to by Dr. White, although, strange to say, he did see Dr. White, for the first time, only a few weeks ago. Finally, the description of Dr. White's case does not correspond to this.

I might add that Besnier, at the Clinical Society of the Hôpital St. Louis, when Hallopeau presented the case previously referred to, mentioned having seen still another case; and several writers cite the case reported in a thesis of Lutz,[3] as general hypertrophy of the sebaceous system, as one of the affection under consideration.

In regard to the true nature of this complaint, whether these bodies called by Darier *psorosperms* are in reality parasites, and whether they are the true cause of the disease, we unfortunately have as yet no means to determine absolutely. All efforts to cultivate these bodies have failed, nor has anyone succeeded in inoculating animals with the disease, although several attempts have been made. The malady does not seem to be communicated by ordinary means, for three of the nine patients were married men, living with their wives, to whom the disease was not communicated. This, however, proves little, for tuberculosis may likewise exist under similar circumstances without infecting others, and it is only very recently that the contagiousness of the latter has been proved; also, tinea versicolor, known to be due to a vegetable parasite, is rarely communicated from husband to wife. But, as already mentioned, Boeck reported a father and two sons affected by the disease, which he considers proof both of contagiousness and of the coccidia as its cause. Unfortunately the cases were only detailed at a society meeting in Norway, and I have been unable to find a full account or description of them. Several able French and other microscopists and naturalists have agreed as to the parasitic character of the bodies referred to, and the evidence seems very strong that they are the producers of the disease in question.

But the most interesting and perhaps important part of the question lies in the fact that more or less similar bodies have been found in the tissues of several other maladies, which are quite distinct from the present one, and from each other, in their clinical features. So marked are these microscopical characters that Darier has proposed the name *psorosperms cutanées* to designate the group in which they should be placed. The first of these diseases is the so-called molluscum contagiosum with which all are familiar. This disease Neisser,[4] Darier, and others cited by them, believe to be due to the presence in the epithelial cells of similar parasites—the so called "molluscous bodies" which have long been known; these resemble in a certain degree the psorosperms already described, and are thought to be identical or at least analogous to them.

These curious round bodies have also been found by Darier, Wickham[5] and others, in that peculiar form of epithelioma of the nipple known as Paget's disease; and Darier further states that Malassez, in 1876, "noticed in a large number of epithelial tumors, cellular bodies, granular or refracting, sometimes encapsuled, which presented certain analogies to the psorosperms of the rabbit," and that Cornil has reported having seen analogous organisms in certain cancers of the uterus.

Here, then, lies the real interest in the study of the disease before us, as well as the important and practical element previously alluded to; namely, the possible results which may come from a thorough investigation and knowledge of the effects in the tissues of an order of parasites, the psorosperms, which have been hitherto unrecognized—if, indeed, the assumption is correct that the three maladies in question are really caused thereby. And you will readily see, that if the observations in regard to epithelioma are correct a great step has been taken in the direction of discovering the cause of cancer. It has been recognized for some time that cancer is occasionally communicated from one person to another, which, to a certain degree, sustains the parasitic origin of the disease. The recognition of the causation of pus by

[1] Journ. of Cut. n. and Gen t o-urinary Diseases, 1889, p. 318.
[2] Boeck Monatshefte für prakt. Derm., Bd. xi. No 3, p. 132.
[3] Hypertrophie Gen. du Syst. Sebacee. Thèse de Paris, 1850.
[4] Viertelj. für Derm. und Syph. 1888, p. 558.
[5] Comptes rendus Congrès Int rnat. de Derm. et de Syph., Paris, 1889, p. 385.

the various forms of micrococci has been prolific of good in surgery; the discovery of the bacillus in tuberculosis is working beneficially in the direction of the prevention of the spread of that disease, and may yield results in regard to treatment; and if it should be fully and positively determined that cancer is due to the presence of *psorosperms*, may we not hope for more rapid progress in its prevention and treatment than has hitherto been attained?

Thus, you see, gentlemen, that cutaneous pathology, always an interesting study, leads the way to investigations which may be of the greatest importance.

In regard to therapeutics, in the patient before us the discovery of the psorosperm in his tissues should give us a clue to a method of treatment which, theoretically at least, promises more benefit than he has received in the past; for, as you have heard, his disease has lasted about twenty-seven years, and he has never been much benefitted by treatment. It remains to be seen how much can be accomplished when treatment is directed against the parasitic element which we have assumed as the cause. Unfortunately, but slight results were obtained during the short time that the Paris cases were under treatment based on this view of the disease. But this need not deter us, for you can readily understand that there may be great difficulties in attacking a parasite *in situ*, and in this disease the bodies referred to are seated very deep in the skin, and penetrate even far beneath the horny plug that you saw me dig out. The existence of the bacilli of tuberculosis and leprosy is now established, but we have, as yet, no means of reaching them *in situ*.

In the present case I shall hope to make many trials of different local remedies in order to reach and destroy the parasite, and shall hope to show you the results. Mercury, iodine, and sulphur, in their various preparations, are the agents we will chiefly depend upon, and some of these covered by impermeable dressings should, I think, succeed in penetrating and destroying the organisms which we believe to exist in the tissues of this man.

THE VALUE OF EXERCISE IN THE TREATMENT OF THE PELVIC DISEASES OF WOMEN.[1]

BY JOHN H. KELLOGG, M.D.,
OF BATTLE CREEK, MICH.

THE propositions which I shall undertake to maintain in this paper are the following:

1. That defective muscular development is a prime factor in the etiology of a large number of the pelvic disorders to which civilized women are subject.

2. That the mode of dress common among civilized women is a cause of deficient and asymmetrical muscular development.

3. That the dress commonly worn by civilized women is productive of such disturbances of the relations and functions of the abdominal and pelvic viscera as directly lead to the production of functional and structural changes in the uterus and its appendages.

4. That properly-graduated exercises, with adjustment of the clothing that will permit free and unrestricted movements of every group of muscles in the body, are of great importance in the management of a large class of pelvic disorders.

The comparative immunity from the disorders peculiar to their sex, as well as from the pain and accidents connected with childbirth, of savage and peasant women, is a fact so well established that the presentation of new evidence is scarcely necessary. Personal study of this subject among Indian women of various tribes, including the primitive Yuma tribe, of New Mexico and Arizona, among Chinese women, and especially among the peasant women of Italy, Germany, France, and England, has enabled me to confirm the observations of Engelmann and others who have given special attention to the question. During my study in European hospitals, I was forcibly struck with the comparatively small number of cases of chronic pelvic disease in women who from early childhood had been trained to muscular labor of a varied character. Such disorders as prolapsus uteri, posterior flexions and versions, and chronic inflammation of the uterus and its appendages are almost unknown among married women of this class who have led chaste lives. Among the peasant women of Europe, pelvic disorders are chiefly those which result from childbirth; and are largely attributable to the carelessness and stupidity of ignorant midwives and the inability to secure the necessary rest and care during the lying-in period. It is surprising to one whose gynecological observations have been chiefly confined to the better classes of American women, that the morbid conditions caused by mechanical injuries, such as lacerations of the cervix and perineum, give rise to comparatively little suffering in women who have a good muscular development. I have frequently seen German and French peasant women in whom the entire uterus, as well as a considerable portion of the bladder and rectum, had been outside of the body for many years as the result of injuries during childbirth or of imprudence afterward, who sought relief not on account of pain, but solely on account of the mechanical inconvenience. This freedom from pelvic diseases and from the extreme suffering which commonly accompanies these disorders in women of the higher classes, may fairly be attributed, in large part at least, to the excellent muscular development resulting from laborious lives.

The young peasant woman of Germany or Italy, who from early childhood has been accustomed to accompany her elder brother in the field, digging, sowing, reaping, threshing out the grain with a flail,

[1] Read before the American Association of Obstetricians and Gynecologists, Philadelphia, September 16, 17, and 18, 1890.

or following the plow, is no more subject to diseases of the pelvic organs than is her brother. If she receives some slight injury to the cervix or perineum in childbearing, she does not thereby become a miserable invalid, and if she experiences any inconvenience, it is merely a mechanical one which she will probably consider scarcely worthy of attention. The peasant woman exposes herself to all sorts of weather without regard to her condition. Her bare feet are exposed to cold and dampness without reference to the approach or presence of the menstrual period. I have seen in that portion of England known as the Black Country, vigorous women old and young engaged in the laborious employment of brickmaking, handling and carrying for many hours each day masses of wet clay which the majority of American women could not even lift. The occupation of these women necessitates constant exposure of the feet as well as the hands to dampness; and yet I was assured by the women themselves, as well as by an intelligent local physician, that they seldom if ever suffer inconvenience from exposures which in many women would produce fatal results. The frugal dietetic habits of these women and their open-air life must have something to do with this exemption from the diseases peculiar to the sex; yet I think this remarkable immunity is more largely due to the unusually symmetrical and vigorous muscular development which they derive from their habits of life. This view is sustained by the anatomical and physiological importance of the muscles in maintaining the position of the uterus and its appendages in relation to the pelvis and to the other viscera of the pelvis and abdomen; and by the relative frequency of uterine displacements and other forms of pelvic disease in women of feeble muscular development who have apparently not been exposed to any cause sufficient to induce such disorders in a vigorous, healthy woman.

The maintenance of the uterus and its appendages in their normal position may be said to be wholly dependent on muscular structures. This may also be said of most of the viscera of the abdominal cavity. The pelvic floor which closes the common outlet of the pelvic and abdominal cavities is chiefly composed of muscles. The vaginal and rectal outlets are closed by muscles. The muscular structures which compose the pelvic floor are sustained by other muscular structures connected with the pelvic bones above. The so-called ligaments of the uterus which play so important a part in maintaining its position are largely made up of muscular fibres. The round ligaments are in part composed of voluntary muscular fibres. The anterolateral walls of the abdomen are chiefly made up of muscles which in a well-developed woman are exceeding strong and firm.

A study of the functions of the round ligaments, the results of which I presented at one of the meetings of the American Association of Gynecologists and Obstetricians, has convinced me that these muscular structures play a most important part in keeping the uterus in position, acting, not only as bands or "mooring-ropes," as Dr. Alexander calls them, but through the muscular contractility of which they are capable. The theory of their action the correctness of which I believe I have demonstrated, is that by contracting simultaneously with the abdominal muscles, they tilt the uterus forward, and thus prevent its being forced backward during violent contraction of the abdominal muscles, the uterus being drawn out of the current of downward pressure. The contraction of the muscles which compose the pelvic floor, when these muscles are properly developed, prevents abnormal lowering of the pelvic floor and of the pelvic organs. A weak, relaxed condition of these structures is usually found in women of feeble muscular development.

Uterine prolapse, retroversion, and retroflexion, and the various forms of ovarian prolapse which accompany these displacements are seldom met with among chaste unmarried women of savage or semi-civilized nations, but are very frequent among young women in America, and among the wealthier classes of all civilized countries. In this country, these conditions, when found in young women, are almost invariably attributed to some accident or imprudence in muscular exercise, such as jumping from a carriage, a fall on the ice, jumping the rope, walking too great a distance, lifting a pail of water, carrying a baby, or some similar circumstance. The baneful effects of stair-climbing have been dwelt upon by physicians as well as over-careful mothers. Not infrequently such light exercise as running a sewing-machine, or standing upon the feet behind a counter, has been charged with producing the worst forms of uterine displacements and other pelvic diseases. I do not say that such things never bring about uterine or pelvic diseases, but I have long been convinced that the causes mentioned above are of slight importance, and that back of them is an etiological factor of a general and fundamental character, the essential nature of which is deficient muscular development.

The mode of dress common among civilized women is productive of pelvic disease, not only by its mechanical effects upon the contents of the abdomen, but by its interference with the normal respiratory movements and the free action of the muscles of the back and abdomen.

In normal breathing, the shape of the chest is changed in the act of inspiration in such a manner that all its diameters are increased. The greatest increase, however, is in the longitudinal diameter

due to flattening of the diaphragm, and in the transverse diameter of the lower part of the chest, due to the action of the inspiratory muscles, and according to Bruger, also in part due to the depression of the abdominal viscera by the contracting diaphragm. In normal respiration in children of either sex, and in both men and women of savage tribes, in which the dress of the two sexes is practically alike, the chief movements noticeable in inspiration are widening of the chest at its lower part and bulging of the abdominal wall. There is at the same time a rhythmical action of the muscles of the pelvic floor induced by the increased abdominal pressure which results from the flattening of the diaphragm.

That the respiratory movements are practically alike in adults of both sexes, I think has been fully established by the observations of Mays and others, as well as by my own studies upon Indian women of various tribes, Chinese women, Italian peasant women, and upon American women whose breathing has never been interfered with by tightly-fitting clothing.

The relation of corsets and tight bands to respiration has usually been studied solely with reference to their influence upon the lungs. The important relation of the respiratory process to the abdominal and pelvic viscera has too often been overlooked, although the disturbance of the normal relation existing between respiration and the circulation of the blood in the abdominal and pelvic viscera is undoubtedly of far greater importance than any interference with the respiratory process occasioned by constriction of the waist.

The effect of inspiration is to increase abdominal tension. This is accomplished by the flattening of the diaphragm, which is facilitated by the increase in the transverse diameter of the lower part of the chest induced by contraction of the serrati and other inspiratory muscles. The effect of abdominal tension is to hasten the emptying of the veins of the portal circulation, in which there is a natural tendency to retardation as the result of the resistance of the hepatic capillary system. In normal respiration, in which the intra-thoracic pressure is diminished by proper expansion of the chest cavity, this emptying of the portal circulation is also facilitated by a sort of suction which draws the blood from the abdominal viscera into the thoracic cavity. Thus, in normal respiration, there is a double action, the tendency of which is to accelerate the circulation in the abdominal and pelvic organs; and it is reasonable to suppose that the health of these organs must largely depend upon a continuous and efficient action of this pumping process which is so essential a feature in the maintenance of the blood-current.

The proper action of the chest may be aptly compared to that of a pair of bellows, the lower ribs to which the strong breathing-muscles are attached, representing the handles. The breathing-apparatus of a woman whose waist is constricted by a corset or tight band is nearly as much embarrassed as would be a pair of bellows with the handles tied together. The upper costal respiration so conspicuous in women who constrict the waist is not seen among savage women, nor in a woman whose respiratory organs have not been restricted by improper clothing. That this mode of breathing is quite abnormal might be inferred from the structure of the upper part of the chest, which is certainly not such as to suggest any considerable degree of mobility. This thoracic breathing is not only abnormal, but as I think I have already shown, it may produce disease. This is true of ordinary respiration, and is most emphatically true of forced respiration, such as is induced by singing or active muscular exercise, under the imperative demand for an increased supply of air. The respiratory muscles are then made to act with undue violence. In consequence of the constriction and the compression of the abdominal walls by the corset, the force is largely expended upon the organs of the pelvis, which are forced down out of position. The pelvic floor is more yielding than the rigid walls of the chest, and is depressed, thus laying the foundation for chronic displacement.

A civilized woman wearing the common dress, cannot expand her waist more than one-fourth of an inch when taking a deep inspiration. The expansion must occur somewhere, and the constriction of the waist forces the expansion to take place at either the upper or lower extremity of the trunk; the greater resistance of the upper ribs and the yielding character of the structures which form the floor of the pelvis cause depression of the pelvic floor to occur with lowering of all the organs which are dependent on it for support.

I have devised an instrument for the study of the influence of constriction of the waist upon the pelvic floor, which consists simply of a lever attached to an upright, and an adjustable support furnished with a vernier, against which one end of the lever plays while the other end rests upon the perineum. The fulcrum of the lever is so placed that the recording end of the lever has an amplitude of movement just five times that of the end placed against the pelvic floor. The instrument can be used with the woman either standing or lying. By the use of this instrument I find that lacing the corset as tight as it is ordinarily worn depresses the pelvic floor from five to twelve millimetres. I have sometimes observed a rise in the pelvic floor of fifteen millimetres immediately after the corset was loosened.

Dr. Trastour, an eminent French physician, has

clearly shown that what he terms the *statique abdominale* has an important relation to the health of the abdominal viscera. The relations of the several organs which occupy the abdominal and pelvic cavities are such that any considerable change in position necessarily results in disease. The stomach, dragged out of place, loses its natural tone, its walls become relaxed, dilatation occurs, and the patient suffers from all the distressing symptoms of gastric neurasthenia. The constant dragging upon the liver and the right kidney may displace these organs. Prolapse of the organs which normally occupy the upper part of the abdominal cavity necessarily compels the displacement of the organs beneath them, leading to what is termed by Glenard, and other French writers, *enteroptosis*. Prolapsed intestines become atonic, from the disturbance of the portal circulation, and not infrequently a pseudo-stricture of the large intestine is occasioned by the bowel folding upon itself, caused by the depression of its central portion, which is more easily dragged down than the ascending or descending portion. Obstruction leads to fæcal accumulation and dilatation. Such disturbances of the relations of the viscera will be found in a large proportion of women suffering from pelvic disorders.

In one hundred cases of pelvic disease taken without selection and in the order in which they came under observation, I found disturbances of the normal relations of the abdominal viscera in ninety-four. The stomach and bowels were prolapsed in all of these cases. There was dilatation of the stomach in more than one-half of them. The right kidney was distinctly movable and had fallen below its normal position in thirty-seven cases. In twenty-seven cases the kidney had fallen so far below the normal position that it was freely movable. In three cases both kidneys were prolapsed. In four cases the liver was very considerably prolapsed; in three cases almost the entire organ was at the inferior border of the lower ribs. In one case, the spleen, which was four times its normal size, enjoyed the freedom of the entire abdominal cavity. When first noticed it was lying between the uterus and the bladder, and was at first thought to be a fibroid growth connected with the uterus.

In the six cases in which there was no disturbance of the relative positions of the abdominal organs, the patients had unusually well developed muscles and the pelvic disease was distinctly traceable to other than mechanical causes.

Mr. Lockwood, of St. Bartholomew's Hospital, London, has shown by elaborate post-mortem studies that hernia is accompanied with prolapse of the mesentery and the attached bowel to the extent of from four to nine inches, and in an address upon the subject he called attention to the influence of tight lacing in producing this prolapse in women.

I have made a large number of measurements of civilized and uncivilized women to determine the relations of the circumference of waist to the height, and other dimensions.

In one hundred civilized women, all eighteen years of age or over, the following are the average results:

	Height. Inches.	Waist Inches.	Percentage of height.
American women	61.64	24.44	39.6
English women brickmakers who wear heavy skirts	60.4	25	43.3
French women	61.6	28	45.4
Civilized Telugu women of India	60.49	24.95	40.6
Chinese women	57.85	26.27	45.4
Yuma women	66.56	30.84	55.2
Civilized man—American	67.96	29.46	43.3

A few words of explanation are necessary in order to present the full significance of the above figures. The civilized corset-wearing American woman has the smallest waist of any of the classes examined. The next in order is the Telugu woman, who suspends her clothing by a cord tightly tied about her waist. Dr. E. J. Cummings, of Ramapatam, Nellore District, India, who kindly made for me the measurements from which the above figures relating to Telugu women are deduced, tells me that it is customary with those women to draw the cord which suspends their clothing as tight as possible; yet the amount of harm done thereby does not seem to equal the mischief accomplished by the American corset. The women brickmakers of England doubtless diminish the size of their waists and produce considerable distortion of their figures by wearing the many heavy skirts suspended by bands drawn tight about the waist. Civilized man, next in the scale, has a much larger waist than civilized woman, yet does not equal in this respect the women who have had an opportunity to develop naturally. The measurements which I have made of savage men and women of the same tribe convince me that women naturally have larger waists in proportion to their height than men.

Properly-graduated exercises, with such an adjustment of the clothing as will afford opportunity for free and unrestricted movements of every group of muscles in the body, are a most important therapeutic means in the management of a large class of pelvic disorders. The exercises which I have employed are, in general, light calisthenics, consisting of free hand and body movements, and the use of wooden dumb-bells, Indian clubs, wands, chest-weights, and various gymnasium apparatus for bringing into play special groups of muscles, walking exercises, breathing exercises, and Delsarte. I also employ exercises with light iron dumb-bells, and light exercises on a

trapeze, swinging rings, and horizontal bars, in suitable cases. The weight of the dumb-bells, clubs, and chest-weights, or other apparatus to be used, is prescribed for each patient, as are also the duration of the exercise and the number of strokes in the use of rowing-machines, and similar apparatus. The employment of a variety of apparatus, and of different forms of exercise, is important, as it not only encourages patients to take a larger amount of exercise than they otherwise would do, but enables them to do so without injury by bringing into play different groups of muscles or different combinations of muscular groups.

The exercise of lying upon the back, and alternately raising the legs from a horizontal to a perpendicular position is particularly valuable. Fixing the legs, and resting the body upon an incline adjusted at an angle suited to the patient, is another special exercise of value.

Resting in a horizontal position, face downward, sustaining the weight upon the elbows and toes, with the body held rigid and free from the supporting surface, is an excellent exercise to develop the muscles of the back and abdomen. This exercise may be varied by alternately raising and lowering the body, resting a few seconds in each position. Drawing the body up from a supine position to an angle of forty-five degrees, by catching the toes on the round of a ladder, is an exercise of great value for patients who are able to take it. It not only strengthens the muscles of the trunk, but at the same time empties the portal veins.

A breathing exercise which I have found of great value is the following: Placing herself in the genupectoral position, the patient takes a deep abdominal inspiration, then expels the breath by forcibly contracting the abdominal muscles, at the same time drawing up as strongly as possible the muscles of the pelvic floor. By this means the round ligaments, if they have not undergone complete degeneration, as well as the abdominal and perineal muscles, are vigorously exercised.

The passive and "active-passive" exercises of the Ling system of Swedish movements are also of great value in these cases, as I can testify after having employed this system for nearly sixteen years. Of great value, also, are manipulations of the abdomen, especially directed to the restoration of prolapsed viscera to their normal position. The circulation is accelerated; prolapsed bowels, kidneys, liver, and spleen, may be restored to position, and thus by making room above, the prolapsed organs of the pelvis are encouraged to resume their normal positions. I have frequently seen excellent results from the employment of abdominal and pelvic massage in conjunction with general and special gymnastic exercises, and various forms of active and active-passive Swedish movements.

The good results of exercise are well shown by the following figures, which represent the gain in strength of the arm, leg, trunk, and respiratory organs respectively, as the result of physical training of the kind referred to. In one hundred women the average gain in two months was as follows:

Arms	16.2 per cent.
Legs	28.4 "
Trunk	28.1 "
Respiratory organs	28.6 "

The average gain of strength for four months was as follows:

Arms	51 per cent.
Legs	55.9 "
Trunk	54.9 "
Respiratory organs	46.6 "

The disproportionately greater gain shown in the longer period, clearly demonstrates the importance of time as a factor in a system of treatment of this kind. There must be time for the muscles to grow.

The great advantage of exercise in this class of cases is best appreciated by the study of individual cases. For example: I have frequently seen the aggregate strength of arms, legs, trunk, and respiratory organs, increased by three months of exercise more than 200 per cent., and I have many cases on record showing an increase of more than 400 per cent. In one instance the rate of increase was nearly 700 per cent.

A CASE OF FOREIGN BODY REMAINING IN THE EYE FOR TWENTY YEARS, FOLLOWED BY ABSCESS IN THE SCLERAL WALL.

By B. L. MILLIKIN, M.D.,
of Cleveland, Ohio.

On March 18, 1871, E. M. O., then about ten years old, was struck in the right eye with a fragment of a musket-cap, which he supposed at the time did not enter the eye. However, the piece was not found. Following the injury the eyeball was greatly inflamed, and he was confined to his room for nearly three months. For two years after this the eye slowly improved, so that vision was pretty fair and he could readily read ordinary type.

The eye gave him no further trouble until about 1883, when he had a severe attack of inflammation which produced almost complete blindness. After this attack the eye again improved, and vision became fair, and he had no more serious trouble until the latter part of 1887, when the eye became painful and injected, and the sight failed.

I first saw the patient, February 28, 1888, when he gave me the above history, and stated that three or four days previously the eye had again become

inflamed, and that he was then suffering great pain through the eyeball and the side of his head

Examination at this time revealed the following conditions:

In the cornea to the outer side of the pupillary margin and a little below the horizontal meridian, was a linear opacity extending outward and slightly downward, perhaps 2 mm. in length. Lying directly behind this and in the same direction was a slit in the iris, extending from near the pupillary border to the outer margin of the iris and so wide toward the periphery that the red reflex of the fundus was readily seen, and also the border of the lens. After several instillations of homatropine hydrobromate the pupil was well dilated, the dilatation being free in all directions except at the border near the slit, where the iris was attached to the anterior capsule. Both the ophthalmoscope and oblique illumination showed, directly behind the slit in the iris, an opaque track through the body of the lens, through which the foreign body had evidently penetrated. In the anterior portion of the vitreous, in the lower outer quadrant, was plainly seen, both through the pupil and the slit in the iris, a grayish-white body of considerable size and projecting into the vitreous. This had the appearance of an encysted body, being quite different from a sarcoma or other neoplasm. There was also a broad choroidal crescent and numerous floating opacities in the vitreous. The vision at this time in O. D. was $\frac{6}{XXXVI}$ and in O. S. $\frac{6}{VI}$.

Directly over the position of this body the sclera and conjunctiva were much injected, and painful on pressure. With slight pressure over this point the body could be seen to project farther into the vitreous. At no other portion of the eyeball was there any tenderness. Tension was normal. He was put upon instillations of atropine solution three or four times daily, and a boric acid collyrium, together with hot applications.

On March 7th he reported that four days previously he had had a very sharp attack of pain through the eyeball and side of the head, but that it subsided after two or three hours, and after that the eye continued to do well. The only change in the appearance of the eye noticed at this time was a peculiar discoloration over the seat of the foreign body as if the sclera was partially eroded.

After recovering from this attack there was no more trouble until September, 1889, when he had another severe inflammatory attack; but owing to my absence I did not see him again until November 27, 1889, when I found the eye in a state of active inflammation, and the vitreous showing numerous opacities, especially in the neighborhood of the foreign body. Under active treatment this attack slowly subsided.

Nothing noteworthy occurred until about the middle of December, 1889, when an enlargement of the sclera began to show itself directly over the position of the foreign body. This increased quite rapidly, so that by December 31st it was quite pronounced. It was somewhat irregular in shape, hard to the touch, and felt as if the sharp edge of the piece of cap might be forcing its way through. Pressure over this point produced much pain, while other portions of the eyeball were quite free from pain. No changes seemed to take place in the interior of the eye.

By January 14, 1890, the eye was free from general inflammation and had been so for some days, but the projection over the foreign body had increased. It was quite circumscribed, and there was no redness except in the immediate neighborhood of this projection. I believed that the piece of cap had become encysted, that gradually, from the repeated inflammatory attacks, the increase of connective tissue, and the action of the ciliary muscle it had worked its way through the retina and choroid and into the sclera, and that it would eventually cut through the sclera externally.

Following ordinary surgical principles the proper procedure seemed perfectly plain, viz.: to give exit to whatever was contained in the swelling. Under cocaine anæsthesia a needle was passed through the most prominent portion of the projection until it came in contact with a hard body. Then a triangular portion of the conjunctiva was dissected from the sclera at this point and a free incision made directly into the swelling. From this three or four drops of pus escaped, when the anterior walls of the sac collapsed.

With a spoon I then scraped out a number of black particles which were hard and under a lens seemed to be metallic. These, I have no doubt, were disintegrated portions of the piece of cap.

As much as possible of the interior of this sac was removed with the spoon, forceps, and scissors. A needle was passed in two or three places directly through the sac and into the vitreous, in order to determine definitely if any hard substance remained.

The extreme thickness of the scleral wall at this point surprised me very much. It certainly was more than one centimetre thick, and notwithstanding the freedom with which I scraped out, and tore out with the forceps, and cut out, with scissors, the hard portions, I did not enter the vitreous or disturb it in the least.

Both before and during the operation the eye and its appendages were thoroughly washed with 1-to-5000 bichloride of mercury solution, and every precaution was taken to keep the wound clean. The cavity of the wound was freely washed with the bichloride solution, and the eyeball was dressed with a compress moistened with the same solution, and with a bandage. The pain from the operation, notwithstanding the very free use of cocaine, was considerable.

The patient recovered without a bad symptom. When an ophthalmoscopic examination could be made I found that the body in the vitreous chamber, previously so prominent, had entirely disappeared and could not be seen through the dilated pupil. By January 22d, all tenderness had subsided, except a slight amount over the wound. Vision = $\frac{3}{XXX}$.

Up to the present time there has been no pain and no tenderness, even over the point of the

wound, where there had been tenderness on pressure for six or seven years at least.

At the present time, on looking well forward through the pupil, there is a slight whitish reflex, but this has not increased since the wound healed, and the opacities in the vitreous have slowly disappeared.

The scar externally is not noticeable, except on the closest scrutiny, and the condition of the eye is better than it has been for years. The patient, a merchant, is able to work steadily, and suffers no inconvenience whatever.

I have given a detailed account of this case because of the unusual features connected with it, and because I have not been able to find any report of a similar case in the literature at my command.

SALOL IN TYPHOID FEVER.

By W. C. CAHALL, M.D.,
of Philadelphia.

During the past two years typhoid fever has been more than usually prevalent in the northwestern section of Philadelphia, and I have been impressed as never before with the fact that the ordinary treatment of this fever is very unsatisfactory. The patient is either vigorously treated with dilute acid, turpentine, or a mixture of tincture of iodine and carbolic acid, all of which, owing to the nausea they produce, are difficult and at times impossible to administer methodically; or, on the other hand, the patient is not treated at all, save when urgent symptoms develop.

At about the beginning of the increased prevalence of the fever in this city I was led, by reading reports of the use of salol for the *diarrhœa* of typhoid fever, to use it as a *specific* remedy in place of the tincture of iodine and carbolic acid mixture. Salol has the advantage of being acceptable to a sensitive stomach, so that its use can be systematically continued, an all-important feature of specific treatment. For a little more than a year and a half I have persistently treated every case of typhoid fever which has fallen into my hands with salol, rarely using anything in addition during the whole course of the fever, and so far with the most gratifying results.

Contrary to my usual custom, I have kept a strict record of every case of this fever that I have treated since beginning the use of salol. After eliminating all the cases in which, from their short, mild course, or from the absence of one or more of the characteristic symptoms of this fever, the diagnosis could be questioned, there remain sixteen cases, of undoubted typhoid fever.

It is not my intention to give a detailed history of each of these cases, but rather to give briefly the results of my observations on the whole.

The dose and mode of administering.—The dose of salol should be at least three grains every two hours, day and night, from the time the diagnosis is made until the morning temperature reaches normal. My experience has been that salol given in pill-form does not give as good results as when given in the form of a powder. This is probably due to the more rapid and complete absorption of the powder in the intestine.

The effects upon the symptoms.—The dry, rough condition of the tongue, so troublesome in this fever, was rarely seen in the sixteen cases, and if present, seldom lasted long.

Salol is insoluble in the saliva and is practically tasteless, hence, in the first few days of the fever, when the stomach is irritable and when there is nausea salol is easily taken, and in its quieting effects is equal to bismuth.

Upon the intestines the effects of the drug are marked; tympany disappears more rapidly than under the use of turpentine, and gives no further trouble throughout the course of the fever. Diarrhœa, no matter how excessive in the beginning, seldom requires any other remedy to control it, but progressively improves. Of hæmorrhage there were a few instances, but in no case was it repeated so frequently as to call for the classical "lead and opium" pill. Tenderness in the right iliac region was invariably present, but diminished without special treatment. Peritonitis supervened in no case. The rose-colored spots were present upon the abdomen and chest of all the sixteen cases, sometimes profusely, but in no case did I notice a second crop.

The effects upon the temperature were noticed within the first few days. Under ordinary treatment the temperature usually rises for the first ten days of the disease, but under the use of salol the temperature seldom rises after the first day of treatment, and after the first week steadily, and more or less rapidly, falls. In several cases the temperature reached normal by a fall of from two and a half to three degrees between evening and morning. In the first case in which this happened I confess that I passed a day of anxiety, fearing hæmorrhage. After the temperature reached normal there was a slight evening rise for two or three days, after which it remained normal.

The pulse does not increase in frequency to the end of the first week when salol is used, but remains full and seldom exceeds one hundred. In none of the cases was the action of the heart such as to require alcohol.

The only untoward effect of salol was the partial suppression of the urine in some cases, but in no case was it necessary to suspend the treatment. I have seen the same symptom produced by turpen-

tine, but it is a point which should be carefully looked after, for in some cases the kidneys might be damaged by the carbolic acid which is set free by the salol. Albuminuria was no more frequent than is usually seen in cases of typhoid fever. All the cases are now in good health.

Complications.—One of the happiest features of this treatment was the infrequency of complications. With the exception of two cases of pneumonia, one of which developed when convalescence was almost established, and a few cases of slight hæmorrhage, there were no complications, and convalescence was invariably rapid and uninterrupted. This is probably largely due to the fact that salol does not disturb the stomach or interfere with digestion, so that the desired amount of nourishment can be given throughout the course of the fever, which cannot often be done when the stomach is continually disturbed by acid, turpentine, or the tincture of iodine and carbolic acid mixture.

Duration.—The average duration of the sixteen cases, not including the two complicated by pneumonia, was seventeen days. Some had a normal temperature at the end of the second week and a few in slightly over three weeks. There were no deaths.

Whatever the differences of opinion as to the cause of typhoid fever it is pretty definitely settled that, after a certain stage, the disease is a septicæmia, due to the ulceration of Peyer's glands. The natural tendency of the fever is to terminate about either the fourteenth or the twenty-first day, and when an intestinal antiseptic, such as salol, is used, which prevents the ulceration from infecting the system, the natural tendency to recovery is increased.

THE ANASTOMOSES OF THE PORTAL VEIN WITH THE SUPERIOR VENA CAVA, INFERIOR VENA CAVA, AND AZYGOS VEIN.

BY F. TISCHER, M.D.,
OF SAN FRANCISCO, CALIFORNIA.

AT the German Chirurgical Congress of 1889 Pietrzikowski spoke of the frequency with which pneumonia follows the reduction of incarcerated hernia, either when taxis alone is employed or when herniotomy is performed. Disregarding those cases in which there are concomitant chronic pulmonary diseases of old persons, such as emphysema and bronchitis; those in which there are coexisting inflammatory processes in the herniotomy wound and peritoneum; and those with complications induced by the inspiration of expectorated particles, such as lobar pneumonia, there still remains a series of conditions for which no plausible explanations exist.

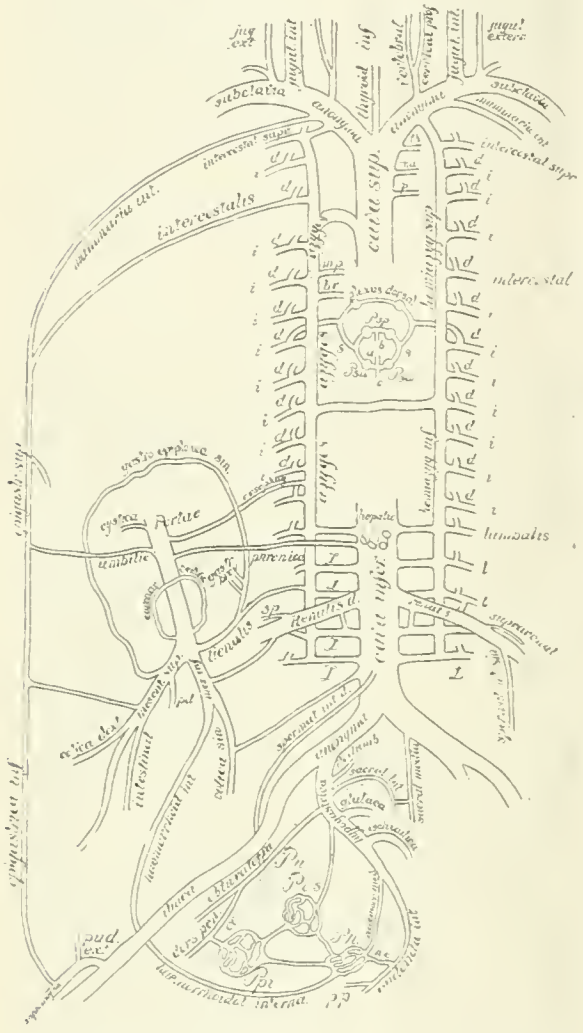
Pietrzikowski maintains the view first promulgated by Gussenbauer, that pneumonia following the recent reduction of strangulated hernia has an embolic origin. The thrombi originating in consequence of the disturbed circulation in the capillaries and small veins of the constricted gut and its mesentery, must, after the restoration of the circulation following the reduction of the strangulated hernia, reach the circulation, and in this way give rise to emboli. As long as the thrombi remain uninfected they act only as temporary infarcts, but if they become infected in the intestinal wall the emboli must, of necessity, lead to inflammation of the pulmonary tissues.

In answering the question, What course must the thrombi, originating in the intestinal and mesenteric regions in the neighborhood of the portal vein, pursue in order to reach the lungs? Pietrzikowski does not deny the possibility of small thrombi reaching the inferior vena cava through the capillary system of the liver and the hepatic vein. Larger thrombi, on the other hand, by avoiding the hepatic capillary system, can reach the lungs through the free anastomoses, between the portal vein and the inferior vena cava. Pietrzikowski makes no special mention of these anastomoses.

Besides the above described anastomoses, others also are of interest. By cutting off the circulation in the portal vein, as occurs in hepatic cirrhosis and in thrombosis of the portal vein, there is the possibility of the formation of a collateral circulation by which the blood of the portal vein can still reach the vena cava. Of course, we must not overvalue the significance of this collateral circulation, as the clinical course of hepatic cirrhosis sufficiently demonstrates.

Further, these anastomoses appear to be the routes for the transmission of infectious matter which originates in ulcerative processes in the intestine, and causes pulmonary inflammations, as is sometimes seen in typhoid fever. Undoubtedly, the lobular pneumonia of typhoid fever is traceable, partly to the scanty expectoration of the bronchial secretion, and partly to the frequent inspiration of inflammatory products from the naso-pharynx. The occurrence of true lobar pneumonia in this disease can be explained as follows: The typhoid bacilli, having passed through the capillary system of the liver, are carried either to the lungs and there find a favorable soil in the catarrhal areas, or a detached thrombus containing typhoid bacilli originating in the infiltrated and ulcerated Peyer's patches passes by means of anastomoses of the portal vein directly to the lungs, and there is firmly lodged without having passed through the hepatic system. Of course, it is strange that in typhoid fever inflammatory areas seldom exist in the liver, notwithstanding that the main branch of the portal is the nearest

route to this organ. One must admit that the liver is as unfavorable a seat for the growth of typhoid bacilli as it is a favorable one for the poison of dysentery which causes suppurative hepatitis. In all probability the infected thrombi originating in



a. vena medullæ spinalis anterior. *b.* vena medullæ spinalis posterior. *br.* vena bronchialis. *c.* vena basivertebralis. *co.* vena communicans obturatoria *d.* ramus dorsalis venæ intercostalis. *he.* vena hæmorrhoidalis externa. *i.* vena intercostalis. *l.* vena lumbalis. *ma.* vena mediastinica anterior. *mp.* vena mediastinica posterior. *p.* vena pericardiaca. *pd.* vena pancreatico-duodenalis. *Ph.* Plexus hæmorrhoidalis. *pp.* vena profunda penis. *Ppi.* Plexus pubicus impar. *Psa.* Plexus spinalis anterior. *Psp.* Plexus spinalis posterior. *Pu.* Plexus uterinus. *Pvs.* Plexus vesicalis. *s.* ramus spinalis. *sp.* vena suprarenalis. *th.* vena thymica.

Peyer's patches, on their way through the anastomoses of the portal vein with the superior and inferior vena cava, occasion the pneumonia.

It may at this point be of interest to consider briefly these anastomoses, as shown in the accompanying drawing, prepared by the plan adopted in Henle's *Anatomy*:

The portal vein, as we know, gathers through its three main branches, the splenic, the superior mesenteric, and inferior mesenteric, and their tributaries, the blood of the stomach, small and large intestine, spleen, and pancreas. From the liver the blood is transmitted to the inferior vena cava through the hepatic vein.

The venous blood of the lower extremities and pelvic region passes through the iliac and hypogastric veins, that of the kidneys through the renal vein to the inferior vena cava.

The hemiazygos vein empties into the azygos vein at the level of the ninth dorsal vertebræ by means of a transverse branch. The azygos empties in the superior vena cava.

In the abdominal cavity the origin of the azygos and hemiazygos veins forms vertical branches connecting the lumbar veins, which empty in the inferior vena cava. The blood of the lumbar veins, therefore, goes partly to the inferior vena cava, and partly to the azygos and hemiazygos veins.

In the thorax the azygos and hemiazygos veins (including the posterior mediastinal and œsophageal) receive the blood of the intercostal veins. The rami dorsales of the intercostal and lumbar veins form the dorsal plexus around the bodies and processes of the vertebræ. They send the rami spinales into the vertebral canal, which receive the blood of the anterior and posterior spinal plexus, and these plexuses communicate through horizontal and vertical branches with each other, and with similarly named plexuses above and below. In the accompanying diagram they are represented in transverse section.

In the abdominal and thoracic portions of the spinal column are the following vertical routes, exclusive of the superior and inferior venæ cavæ: Azygos, hemiazygos, the vertical communications of the dorsal plexuses outside of, and of the plexus spinales anterior and posterior, within the canal.

In the anterior abdominal wall a vertical communication exists between the saphenous and internal mammary veins, which is due to the anastomosis of the inferior epigastric vein with the superior epigastric. From the internal mammary vein the blood is carried either to the anonyma brachiocephalic, or, through the communications of the internal mammary with the intercostal veins, to the azygos and hemiazygos veins.

It must also be noted that the renal veins are connected just as closely with the azygos and hemiazygos veins, and also with the lumbar veins, and with those of the superior intercostals, which, with the azygos and hemiazygos empty into the innominate brachiocephalic veins.

According to Professor Braune,[1] the veins of the thoracic and abdominal cavity have no valves.

The communications between the portal vein and the superior vena cava, inferior vena cava, and azygos vein, are as follows:

1. Communications between the mesenteric veins and those of the abdominal wall—superior and inferior epigastric veins. The blood may go either through the inferior epigastric to the long saphenous vein, and thence through the iliac to the inferior vena cava, or through the superior epigastric to the internal mammary, and thence into the superior vena cava.

2. In those cases in which the umbilical vein remains unobliterated the blood from the portal vein can reach the superior epigastric in an abnormal direction. From there the blood courses in the way described in sub-head 1, or through lumbar and gluteal branches. Bamberger states that the umbilical vein is not infrequently found unobliterated. When the umbilical vein remains open, and in hepatic cirrhosis, we have an obliteration of the portal vein, and a dilatation of veins, forming the caput medusæ, simultaneously takes place. When the umbilical vein is obliterated this dilatation occurs as the result of communications between the mesenteric and superior epigastric veins as described in sub-head 1.

3. Anastomosis of the internal hæmorrhoidal vein (a branch of the inferior mesenteric vein) with the hæmorrhoidal plexus. Through this vein many communications with the hypogastric vein are found—through the middle hæmorrhoidal vein, through the external hæmorrhoidal and internal pudendal veins, through the communicating obturator to the obturator, or through the vesical plexus.

4. Anastomosis between the mesenteric vein and inferior vena cava.

5. Anastomosis between the mesenteric and renal veins.

6. Anastomosis between the splenic and azygos veins.

7. Anastomosis between the small veins of the capsule of Glisson (branches of the portal vein), or between the coronaria ventriculi and the phrenic vein.

8. Anastomosis of the portal vein with the œsophageal, a branch of the azygos.

Finally, new anastomoses between the portal vein and the veins of the abdominal wall may be formed in the adhesions between neoplasms and inflamed viscera within the abdomen.

It would occupy too much of the reader's time to mention in this paper all the possible routes that can carry thrombi formed in the portal system to the right heart, and from there to the lungs. These routes can be seen in the accompanying diagram.

In the diagram the liver and stomach are represented everted, so that the circle of the coronaria ventriculi, and that which the splenic makes with the gastro-epiploicæ, are above. Further, in order to make the anastomosis more clear, many of the veins are represented as short branches only. The plexuses in and about the spinal column are represented in transverse section at the level of the seventh dorsal vertebra; the communications of the intercostals with the internal mammary at the third intercostal space.

The relation, as represented in the chart, of the hemiazygos to the azygos is not the same in all cases. The hemiazygos more frequently empties into the upper portion of the hemiazygos accessoria, which carries the blood of the upper branches of the intercostals by a complicated route to the azygos, and, through the superior intercostal, communicates with the innominate vein. The lower vein, the hemiazygos, empties into the azygos at the level of the ninth dorsal vertebra. Usually, between the hemiazygos and the accessory hemiazygos a small branch carries the blood from one or more intercostal spaces to the azygos.

GENERAL PARESIS OF THE INSANE.

BY GERSHOM H. HILL, M.D.,

SUPERINTENDENT OF THE IOWA HOSPITAL FOR THE INSANE, INDEPENDENCE, IOWA.

THE symptoms of general paresis of the insane were first noticed and described about the year 1800. Esquirol described a typical case of the disease under the name of monomania. His pupil, Bayle, completed the study and gave an accurate description of the disease in 1825. Forty years ago general paresis had not been recognized in this country, but of late years the disease has made its appearance in all our institutions for the insane, and statistics show that it is increasing with alarming rapidity. For this reason, and because of the difficulty of early diagnosis, I have thought that the subject would prove interesting. Furthermore, the disease is important because it is not only incurable, but is sure to terminate in death within a few years.

I use the term *paresis* instead of *paralysis* because the loss of power is slight in the early stages and seldom in its course is any set of muscles or part of the body rendered completely powerless. As the name indicates, the characteristic feature of this disease is a paralysis that is general, but incomplete, occurring in a person whose mind is unsound. It is not my purpose to review the literature of this subject, but to state conclusions reached by my own experience.

Among thirty-seven hundred cases of insanity

treated at the hospital at Independence, there were forty of general paresis. There were seven cases in the first one thousand admissions, seven in the second one thousand, ten in the third one thousand, and sixteen in the last seven hundred. Although the disease was later in making its appearance in Iowa than in the eastern and more populous States, yet cases occur with increasing frequency. There were but two women among the forty cases admitted.

While one-third of the insane in Iowa are foreign-born, only one-fourth of the paretics were foreigners, therefore we cannot claim that the disease is imported.

The oldest paretic was fifty-nine years old when admitted to the hospital, and the youngest was twenty-six; the average age was forty-two years. Hence it will be seen that paresis attacks men while in their most active years.

Ten of the cases were single, and thirty were or had been married. While more than one-half of all our insane men are single, only one-fourth of the paretics are unmarried, consequently the disease is more likely to occur among the married than among the single.

The occupations represented by the forty cases are as follows: Merchants and salesmen, nine; mechanics, seven; laborers, seven; farmers, six; railroad men, four; hotel men, two; lawyer, one; editor, one; and insurance agent, one. One of the women was a dairyman's wife, and on account of her husband being an invalid she not only worked excessively, but was obliged to tax her faculties to the utmost in order to continue the business and support the family. The other woman was an artist, and her reputation for virtue was not the best.

So seldom does an insane woman have general paresis in our population, which is largely rural, that it is hardly worth while to include the sex in our statistical investigations.

Three-sevenths of our insane men are farmers, but only one-seventh of those having general paresis are farmers. While the same number of paretics were day laborers, there are only half as many laborers as farmers among the insane men. On the other hand, the proportion of professional railroad men and merchants who have paresis is large. This fact leads to a two-fold conclusion concerning the causes of this disease, namely, that business men are much more subject to it than those whose employment is chiefly manual labor; and that it is engendered by the vicissitudes and vices of city rather than those of country life. In a New York City asylum a few years ago, among sixteen hundred insane men two hundred and five were found to have general paresis. So far as my own observation extends, the disease is seldom brought on by purely intellectual pursuits.

With regard to education, I may say that paretics are seldom thoroughly educated, nor, on the contrary, are they often very illiterate. They are usually men of a nervous temperament, possessing an unusual amount of energy, disposed to tax their faculties and at the same time to find enjoyment in the indulgence of their animal appetites.

Among the predisposing causes heredity stands first in importance and frequency, and was discovered in twelve of the forty cases. In two there was a history of sunstroke, and in one a history of an injury to the head.

As to the exciting causes, the excessive and continuous use of stimulants is more likely to produce this than other forms of insanity, and the same may be said of excessive venery. More than half of my cases had used intoxicants freely; but several of the men who had formerly been intemperate had not used stimulants for a few years before becoming insane. On the other hand, in most cases of excessive sexual indulgence the habit existed when the insanity became apparent, so that it is impossible to determine whether this habit is the result of a morbid perversion of the appetite, and is only an early symptom of the disease, or whether it sometimes causes paresis. A history of syphilis was found in a few cases, and no doubt syphilis produces this as well as other forms of mental derangement. In men of limited capacity and education, whose minds are not well balanced, overtaxing the mental faculties produces paresis. In this as in other forms of insanity, several of the causes, both predisposing and exciting, are usually present in a case, so that it is difficult to decide which is the chief cause.

In persons having paresis it is usual to find the will or the emotional nature holding sway over the intellect.

Sleeplessness, impairment of the memory, an irritable disposition, changeableness in moods, carelessness in dress and in business affairs, with an inclination to do foolish things, are among the early symptoms; later the patient may have periods of excitement or anger, he may fail to distinguish between his own and the property of others, and may pilfer trifles which strike his fancy. Next he may be inclined to speculate or to assert that he has unlimited possessions. Some are disposed to make presents indiscriminately; others do not claim riches or manifest extravagance, but reveal a comfortable, complacent, self-satisfied frame of mind, although their actual pecuniary condition and their business or domestic relations may be most embarrassing. The tendency from first to last is to weaken all the faculties until the patient is too demented to take any interest in his own relatives and is unable to tell his name.

While these changes are taking place in the mind

the disease of the nervous system is making more or less rapid progress in the impairment of muscular power. The first change to be noticed is a tremor of the lips or facial muscles when efforts of speech are made, especially when the patient is excited; the tongue is unsteady when protruded, and hand-shaking may be done in an awkward and uncertain manner. In the course of time the gait becomes ataxic, the walk is unsteady or shuffling, a lack of endurance becomes apparent, and the patient is worn out by very moderate efforts at work. Hesitation in speech is generally noticed, and an inability to command names and ordinary words, hence conversation is fragmentary and desultory, and aphasia may be well marked. When inquiry is made from day to day and month to month as to the health of these patients, the stereotyped reply is "first-rate."

Finally, these poor unfortunates become disorderly in their conduct, filthy and destructive in their habits, helpless and bedridden. Some of them have epileptiform or apoplectiform seizures, which in the early stages of the disease are usually short and fully recovered from, and the hemiplegia which may thus be brought about usually disappears in a short time. When the patient has lost his powers, both of body and mind, life ends after a prolonged period of unconsciousness.

In none of the cases admitted to our hospital had general paresis been diagnosed, although it might have been, in some instances, had the certificates required of the examining physicians a statement of the form of insanity.

The average duration of the disease in these forty cases, before they were sent to the hospital, was eight months; the shortest time it had existed was one week; the longest time before the patient was admitted was thirty months. In my opinion very few cases run their course without being sent to a hospital for the insane. At times they are lawless and too troublesome to be kept at home. In one-fourth of the cases there was a remission in the mental manifestations of the disease so that such patients seemed quite natural for a time, and some were permitted to visit their homes for a few months. The average duration of the disease in twenty-five cases was two and a half years.

The morbid anatomy as it appears macroscopically shows a "wet" brain. The large quantity of cerebro-spinal fluid between the membranes and in the sinuses indicates atrophy of the brain-substance. In a few cases, however, in which the disease runs a rapid course, the brain is engorged with blood, completely filling the cranial cavity, and in such cases there is a diminution of the serum. The dura is somewhat thickened, the pia opaque and more or less adherent to the convolutions, especially upon the vertex. The arachnoid is also thickened and opaque, and certain parts of it are marked by a granular roughness.

The brain itself is generally pale, flaccid, and diminished in consistence, except when the disease has run a rapid course and been characterized by active mental symptoms, when the cortical substance is likely to be dark and hyperæmic. The cerebellum is also hyperæmic, and less firm in consistence than natural. The membranes of the cord are in about the same condition as those of the encephalon.

There is necessarily great diversity in the appearance of microscopical sections on account of the varying conditions due to age, duration of the disease, a high or low degree of brain development, the effects of alcoholism, and of diseases in other organs of the body. The capillaries are usually dilated and sometimes filled with blood-corpuscles. There is hypertrophy and hyperplasia of the neuroglia, also granular degeneration of nerve-fibres and cells of the cerebral cortex and of the fibres of the subjacent white substance.

The disease usually begins in the medulla, is at first chiefly localized here, and later involves the cord.

Recapitulation.

1. As a rule general paresis affects men only.
2. Its victims are men in the full vigor of life, and generally from the middle classes of society.
3. It is usually caused by excesses, either in the use of stimulants, in venery, or in the application of body and mind to business affairs.
4. From its onset it is steadily progressive, is absolutely incurable, and runs its course in a comparatively brief period.
5. It has two separate sets of symptoms, muscular and mental.

THE PROFESSIONAL, MORAL, AND LEGAL RESPONSIBILITY OF THE OBSTETRICIAN IN CASE OF DEATH FROM PUERPERAL SEPTICÆMIA.

By MANNING SIMONS, M.D.,

Professor of Surgery in the Medical College of the State of South Carolina, Charleston, S. C.

"The professional, moral, and legal responsibility of the obstetrician in case of death from puerperal septicæmia," is a question that seems to have dawned upon the profession everywhere. The Chicago Medico-Legal Society[1] recently discussed the question "Whether the failure of a physician to accept and practise the precepts of antiseptic midwifery should make him legally liable and responsible if puerperal fever develops in his puerperal patient during his attendance upon her."

Dr. W. L. Richardson, of Boston, sounds the

[1] March, 1888.

keynote of the public, and to some extent of the professional sentiment on this subject, when he says:

"Since the appearance of Koch's work on bacteria obstetricians all over the world have been endeavoring to find out how best to banish puerperal septicæmia from the lying-in chamber and maternity hospitals, and no one who has carefully investigated the subject denies that it can be banished, if the proper prophylatic measures are taken."

In these views of Dr. Richardson we recognize the prevailing idea that there is a large number of diseases the occurrence of which indicates either negligence or ignorance.

The list of such diseases is increased from time to time by the laboratory work of the pathologist and bacteriologist, and it becomes the duty of the practical, "every-day" doctor to apply to the new views and theories the test of the clinic.

It seems an opportune time to discuss this matter, for in a recent article Dr. W. T. Lusk says:

"There has likewise been, without doubt, an improvement in results among well-to-do classes. Among these there is a widely-diffused belief that puerperal fever is a preventable disease, and that for its occurrence the physician should be held responsible, and this leads to greater painstaking on the part of the latter, even when he is disinclined to accept deductions from modern scientific teaching."

Other medical writers go even further in this direction, and in illustration of this tendency to hold the obstetrician responsible for unfortunate results, we find in the address on obstetrics before the last meeting of the American Medical Association the following strongly-expressed opinion:

"There are a few simple rules pertaining to the subject of aseptic midwifery, and they must be scrupulously and delicately adhered to by every physcian who practises the obstetric art. Failure to do this is to shoulder an awful responsibility, and the consequences of such neglect would be indefensible either in a court of morals or of law."

In order that such responsibility should rest upon the obstetrician, negligence or gross ignorance must be shown, or, to express it in the words of another:

"The surgeon must adopt the means and apply the skill well settled by the highest lights of his profession. He must possess and practically exercise that degree and amount of skill, knowledge, and science which the leading authorities have pronounced as the results of their researches and experience up to the time or within a reasonable time before the issue or question to be determined is made."

The first point, then, for us to consider, is the present state of professional opinion as to the causes of puerperal septicæmia.

All cases of puerperal septicæmia are certainly not alike either in their symptoms and course, in the mode of infection, or in the extension of the disease. It would be a useless task to endeavor to detail the theories that have been advanced to explain the facts, but it is almost a certainty that the general tendency is to attribute the occurrence of puerperal septicæmia to the entrance of disease-producing organisms, or of organisms capable of causing decomposition, and producing poisons chemical in their nature in the discharges of the parturient woman. The poisons are probably absorbed from the lesions in the genital tract, lesions which are liable to occur during the most natural labors. It is even held that it is possible for absorption of septic matter to take place through the unbroken mucous membrane.

We may recognize, then, two classes of cases of puerperal septicæmia:

First. Those in which the poison or septic material originates within the patient, so that she infects herself, the disease then being called *autogenetic*.

Second. Those in which septic matter is conveyed from without and brought in contact with surfaces in the genital tract that are capable of absorbing—the disease then being called *heterogenetic*.

According to the more recent theories, microorganisms are the ultimate cause of the disease in both of these classes.

In the first class there is probably that state called septic intoxication. In the second class there is a true septic infection.

In the first or the so-called autogenetic forms, the decomposition and putrescent changes in the retained coagula, portions of placenta, or membranes could not occur were it not for the presence of microörganisms, not necessarily pathogenic in theira nture; whilst in the second class there are probably introduced peculiar pathogenic organisms, the manifold multiplication of which in the system produces the septic fever.

The cases of the latter class are characterized by a very short incubation, by a rapid course, and by the absence of such marked local lesions as are almost invariably met with in the class of cases first mentioned.

It is by no means certain that these poisons are always directly introduced by the fingers of the obstetrician or the nurse, but it is here that much of the responsibility lies. It is more than probable that the air loaded with germs in certain localities is itself a sufficient means.

This, in brief, is a summary of the present views upon the causation of puerperal septicæmia, and it remains for us to inquire as to what extent, if any, the application of the principles and details of antisepsis and asepsis has operated to reduce the amount and mortality of puerperal septicæmia.

According to Lusk, in a recent article, the ratio of deaths from puerperal septicæmia in New York

City has by no means kept pace with the increase of the population.

Not long since it was thought necessary in order to escape epidemics of puerperal septicæmia in hospitals, that lying-in wards should be placed in temporary buildings.

Now with the more modern plans of management it is found that whereas formerly these institutions furnished nearly one-sixth of all the fatal cases of puerperal sepsis, they, when properly equipped and organized, are the safest places for parturient women. This safety has been secured by modern methods of treatment based on recent observations.

According to the writer of the Address on Obstetrics, already referred to. "there are a few simple rules pertaining to the subject of aseptic midwifery." Our duty will be to enumerate these simple rules as taught by modern authorities. Our next inquiry, and that to which it appears to me discussion should be particularly directed, is as to which of these rules accord with the present state of obstetrical science, and which, therefore, should be accepted in order to avoid the charge of negligence or ignorance.

Before summarizing the present views I will call attention to the influence exercised by the surroundings of the patient in producing puerperal septicæmia independently of conveyance of the poison to the patient by the physician or nurse.

Among the factors to be considered with the surroundings of the patient are the water-supply, the public drainage, the plumbing, and the existence of diphtheria, scarlet fever, or erysipelas.

If these are admitted to be the means of causing puerperal septicæmia, and if it is also admitted that the essential causes of the disease are microörganisms which make their way by one means or another into the blood and tissues of the puerperal woman, then asepsis and antisepsis are properly applied to midwifery.

In treating of the prophylaxis of puerperal diseases we should consider:

First. The surroundings of the patient, including personal and public hygiene.

Second. The management of the patient herself, in order to insure asepsis.

Third. The preparations and precautions to be taken by the physician and nurse before entering upon the management of a case of labor.

It is not necessary for us to occupy ourselves with the matters included in the first class, for it can scarcely be claimed that the obstetrician is responsible for personal or for public hygiene.

The patient at the commencement of labor should receive a full bath, and after this a rectal injection.

The lower abdomen, the inner surfaces of the thighs, the labia, and the anus are scrubbed with soap and water, then washed with pure water, and finally disinfected with a 1-to-1000 solution of corrosive sublimate. The vagina is douched first with soap and water, and then with a 1-to-5000 solution of corrosive sublimate. Most important is the management of the third stage of labor, in order to guard against the retention of clots, pieces of placenta, or membranes, in which decomposition may occur.

The Credé method of expelling the placenta is recommended, and ergot is given to secure thorough uterine contraction, and to prevent thus the formation of clots in the uterus when relaxation takes place, after the removal of the placenta.

In all cases after labor the vagina is douched with a bichloride solution, 1 to 5000.

In cases of protracted labor, of high forceps operation, of version, or of any manipulations by means of which air is admitted to the uterine cavity, the douche of sublimate solution, after preliminary vaginal irrigation, is carried to the uterine cavity. The external parts are dusted with iodoform and are covered with a piece of gauze freshly wet with 1-to-5000 bichloride solution, and over this is placed a pad of oakum. The dressing is changed once in six hours, at which time the genitals are scrupulously cleansed. During the puerperium no vaginal douches are given. These are the precautions as applied to the patient.

The third indication requires that the physician and nurse should, if possible, have taken baths. The physician should not have visited the dead-house, or the wards of a hospital, or the rooms of private patients in which erysipelas, septic wounds or diseases, or the exanthemata are being or have been treated. The hands should be washed and disinfected before each examination during or before labor, and especial attention should be paid to the finger-nails, as the furrows around and beneath them are often the lurking-places of disease-producing matters. Examinations should be made as infrequently as possible.

These indications apply to the nurse with as much force as to the physician, and under no circumstances should the nurse be permitted to make a vaginal examination.

These, in brief, constitute the "simple rules" previously alluded to. But there is scarcely a point in these rules concerning which the opinions of all agree. Thus the pad of oakum over the vulva has been sneered at. The prophylactic douches have also been criticised, especially the ante-partum douches. On the other hand, it has been advised to irrigate the vagina during labor at intervals of two hours with a quart of corrosive sublimate solution. It has also been recommended that the vagina be first thoroughly rubbed with a preparation of creolin and mollin, and then irrigated for ten

minutes with a creolin solution. There is also much difference of opinion as to the use of the douche during the puerperium, and the propriety of intra-uterine douches. It is recommended, however, by many that the bichloride solution be used, of a strength of 1 to 3000, and that an iodoform "bacillus" be introduced. Finally, to add to our confusion, we are reminded by Dr. William L. Richardson, of Boston, that corrosive sublimate douches are a most dangerous weapon.

The question that should be discussed, it seems to me, is, whether these rules should be observed in detail, in order that the obstetrician may escape the charge of negligence or ignorance, and if not observed, to what extent we should depart from them.

Considering the subject as I have endeavored to present it, as briefly as possible, one is impressed with the truth of the following words of an eminent jurist, "It will tend to encompass a most important and anxious profession with such dangers as to deter reflecting men from entering into it."

CLINICAL MEMORANDUM.

MEDICAL.

Two Cases of Vesical Calculus relieved by Buffalo Lithia Water.—CASE I. At three o'clock in the morning of January 2, 1890, I was called to see a woman who I found in a uræmic convulsion. This I controlled by inhalation of chloroform, and after securing diaphoresis I returned home.

Three hours later I was again called in haste, when I found her suffering from an attack of renal colic, which I relieved by a hypodermic injection of morphine. I then obtained from her the following history:

Age thirty-eight years; a widow; father living and healthy; mother died of phthisis at the age of forty-one years. The patient had enjoyed good health until about two years ago, when she began to suffer from dyspepsia. She had been treated for ulcer of stomach, dyspepsia, inflammation of bowels, etc., but had never been examined for stone in the bladder. She had suffered from attacks of renal colic for the last eighteen months, which were increasing in frequency.

In the afternoon I was called again, and found that she was bleeding from the urethra. I examined the urine and found a large number of small calculi, and one the size of a pea, and angular, which, no doubt, had caused the hæmorrhage. I ordered her to take three drachms of solution of potassium citrate, and ten minims of deodorized tincture of opium three times daily, and Buffalo lithia water *ad libitum*. On January 5th I examined her for stone, and found a hard crust on both the anterior and posterior wall of the bladder. Washing out the bladder twice a week caused much improvement in the cystitis, and after the fifth week of this treatment I could not detect the crust, but found in the urine large fragments of calculi. Now, after using the lithia water for three months, the patient is in excellent health, the urine normal, and the cystitis entirely well. The potassium citrate and opium were not given after the second week.

I have used Buffalo lithia water in similar cases with very flattering results, especially in cases with marked lithæmia.

CASE II.—The patient, a soldier, aged sixty-one years, had suffered from cystitis, constant dribbling of urine, insomnia, and chronic diarrhœa, for nearly twenty years. He had been treated for stricture, and was at one time told that he had a stone in his bladder, although he was never examined with a sound. He finally permitted me to examine him for stone, under ether. After some difficulty in passing the sound, I found what I supposed was a large calculus. He would not consent to the operation of lithotomy, and in order to relieve him, I ordered potassium citrate and opium, and Buffalo lithia water *ad libitum*, as in Case I.; for the diarrhœa, I gave the following mixture:

R.—Deodorized tincture of opium Castor oil	of each 2 drachms.
Turpentine	1 drachm.
Acacia	a sufficient quantity.
Camphor water .	sufficient to make 2 ounces.

Dose, one teaspoonful three times daily.

The bladder was washed out once a week with a solution of boric acid. The urine was frequently examined. On the first examination it contained an excess of urates, uric acid crystals, pus, and blood-corpuscles. After the fourth week the urine contained no pus or blood-corpuscles, but there was still an excess of urates. The patient's general health improved. At the beginning of the eighth week of treatment the urine was nearly normal, the dribbling had stopped, and the diarrhœa had diminished. At the end of the tenth week the irritability of the urethra and bladder was so much less that the sound could be passed without anæsthetization. The calculus was apparently very much decreased in size, but seemed harder. At different times I had noticed small crust-like concretions in the urine, which, no doubt, were from the calculus. It is a question whether the lithia water or the boric acid caused the stone to crumble.

At present the patient is in good health, with no dyspepsia, insomnia, or cystitis.

200 "D" STREET, WASHINGTON, D. C.

MEDICAL PROGRESS.

Myxœdema and Cretinism.—BIRCHER (*Sammlung klinische Vorträge*, No. 357) believes that the secondary symptoms of myxœdema, namely, hypertrophy of the left ventricle, pallor of the skin, slow pulse, œdema, serous effusions, etc., are dependent upon the associated endarteritis, hepatitis, and nephritis, and that the latter are probably due to alterations of the kidneys. The nutritive fluids are changed, the blood is watery, the number of red corpuscles is diminished, and mucin is deposited in the tissues. The primary cause of all the symptoms is atrophy of the thyroid gland; after total extirpation also a symptom-complex appears which resembles myxœdema in every particular. This operation-myxœdema begins with more severe symptoms, and runs its course more rapidly than the atrophic myxœdema.

The thyroid gland seems to be necessary to life, and, according to the author, apparently prevents the formation of mucin in the tissues, a function that cannot be assumed by other glands. If in a dog the thyroid is extirpated from the neck and the thyroid of another dog is implanted in the peritoneal cavity the animal will live, whereas if there is no implantation of the thyroid the dog will die. It is also possible that the gland, situated in whatever part of the body, supplies the organism with necessary fluids.

Bircher then describes the symptoms following total extirpation of the thyroid for goitre, as seen in five women. In three cases, soon after extirpation, serious symptoms of myxœdema became apparent but spontaneously disappeared. The fourth patient died with epileptiform convulsions soon after the operation. The fourth patient was a cretin, and after the extirpation the characteristic cachexia and tetanic and epileptiform symptoms appeared. Implantation of a piece of thyroid gland in the peritoneal cavity was followed by an improvement of all the symptoms, which, however, was only temporary. After a second implantation there was improvement again which continued, and the patient is now—three months after the implantation—well and able to work.

The author believes that the cretinoid degeneration is an infectious disease, the germs of which are found in drinking-water. Of its symptoms the most important and constant are hypertrophy of the thyroid and arrested growth of the bones, particularly those of the skull. There are three forms of the disease, namely, endemic goitre, the least serious; endemic deaf-mutism; and endemic cretinism (idiocy), the most serious. The author concludes his paper with the following propositions:

1. Myxœdema is a sporadic disease resulting from the loss of function on the removal of the thyroid and is a dyscrasia that chiefly affects the growing organism.

2. Cretinism is an endemic disease caused by long-continued infection, which causes hypertrophy of the thyroid, and if occurring during body-growth causes irreparable arrest of development. — *Centralblatt für klinische Medicin*, October 11, 1890.

Treatment of Prolapse of the Rectum.—Mr. Harrison Cripps (*Lancet*, October 11, 1890) contributes a very practical article on the treatment of prolapse of the rectum. In children, he writes, palliative treatment is often very satisfactory, provided that the condition is not caused by phimosis, vesical calculus, polypus of the rectum, etc. If the child is thin, good food and cod-liver oil should be given in order to restore the fat in the ischio-rectal fossæ, the absence of which doubtless facilitates the descent of the bowel. If prolapse can be prevented for two or three months a cure will probably be effected, and with this object in view great care must be exercised to prevent constipation. The stools must never be passed while the child is in a sitting position, but while lying upon its side at the edge of a bed. If, with the child in this position, while the fæces are passing, the mother will draw one of the buttocks upward so as to displace the anus from the median line, prolapse will almost certainly be prevented. The child should remain on its side for some time after the stool, and a pad, held in place by a T-bandage, should be worn for one or two hours. If these measures are carefully carried out operative treatment will seldom be required.

In adults, palliative treatment seldom cures, although it may be tried before resorting to an operation. The patient should be cautioned against straining and should turn on the side as far as possible while passing a stool. Every passage should be preceded by an enema of eight ounces of warm water, and followed by a smaller enema —one ounce— of cold water. If there is superficial ulceration a drachm of tincture of catechu may be added to the last enema.

With regard to operative treatment, in a few severe cases complete removal of the prolapsed portion may be necessary, but before advising such a procedure, the risk of the operation and the probability of causing a stricture of the rectum should be considered. For these reasons complete removal should be reserved for cases in which other measures have failed, and usually linear cautery will be sufficient to effect a cure. This operation is performed as follows: The rectum having been emptied, the patient is etherized and placed in the lithotomy position, and by manipulation the bowel is protruded. With a hot iron four lines are then burned in the long axis of the bowel, one in front, one behind, and one on each side. Paquelin's cautery is not suitable for this purpose; it is too hot when applied and cools too rapidly. The lines should commence within the apex of the protrusion and should terminate at the margin of the anus. They should be about one-fourth of an inch wide and deep enough to sear thoroughly the mucous membrane but not to destroy it. If dilated veins are crossed they should be tied on each side of the burn. The bowel should be returned as quickly as possible, or congestion and swelling may prevent replacement. If the bowel does not protrude at the time of the operation the cauterization may be performed with the assistance of a large duckbill speculum.

After the operation a rubber tube, seven inches long and one-third of an inch in diameter is passed into the bowel for five inches. Strips of oiled lint are then inserted and the space between them and the tube is packed with cotton dusted with iodoform. After forty-eight hours the dressing is removed, the parts are thoroughly washed, and a clean dressing is applied. After a few days the dressings may be dispensed with, but the tube should be kept in place for ten days or longer. The bowels should be confined by means of opium for ten days and then opened by a full dose of castor oil.

Anæsthetic Spray.—Dr. B. W. Richardson states that a solution of five grains of carbolic acid in five ounces of ether used as a spray is an excellent local anæsthetic. The anæsthesia produced appears before the skin is hardened by the cold—an advantage in cutting operations. If deep incisions are required a continuance of the spray upon the tissues causes very profound anæsthesia, and dissection can be continued without pain. The anæsthesia has the additional advantage of being more prolonged than that produced by other local anæsthetics, and there is little or no pain after reaction has taken place. The disadvantages of this spray are that in some instances the wound heals slowly and by granulation, leaving an ugly scar; and that in a very large wound there is danger of carbolic-acid poisoning. Dr. Richardson

recommends use of the spray chiefly in cases of ulcerating cancer with pain and an offensive discharge.—*London Medical Recorder*, October 18, 1890.

The Uses of Keratin.—DRS. UNNA and BEIRSDORFF recommend that drugs which irritate the gastric mucous membrane, such as digitalis, squills, salicylic acid, iodide of iron, etc., be given in the form of pills coated with keratin, or in capsules of the same substance. Drugs which diminish the activity or which neutralize the acidity of the stomach, such as tannic acid, nitrate of silver, and alkalies, should be given in the same way. A coating of keratin is also desirable when prescribing drugs that are required to act on the intestinal mucous membrane alone, and is especially valuable in the use of drugs which are given for the purpose of destroying intestinal worms, but which, if introduced into the stomach in the ordinary way, are absorbed to such an extent as to cause toxic symptoms, or to reduce their germicidal activity.

Keratin is obtained by treating shavings of horn with ether, alcohol, and an acid. It possesses the peculiar property of being insoluble in the stomach, but freely soluble in the intestines.—*Lancet*, October 18, 1890.

Menthol in the Treatment of Diphtheria.—For two years WOLF (*Wiener medizinische Presse*, October 12, 1890) has treated his cases of diphtheria by local applications of menthol mixed with sugar in the proportion of one or two parts of the former to twenty of the latter, with excellent results. The powder is applied by means of a large brush at short intervals. Frequently after removing the brush from the throat a shred of membrane is found attached to it. This is washed off, the brush is partly dried, dipped into the powder, and again applied, repeating the process until no membrane can be brought away. By the second or third day improvement is manifest, and a clean surface is soon found in place of the membrane.

"Boric-acid Massage" in Diseases of the Conjunctiva.—In the treatment of granular and follicular ophthalmia and similar conditions, DR. W. M. BEAUMONT (*Lancet*, October 18, 1890) recommends rubbing the conjunctiva with finely-pulverized boric acid. The method is carried out as follows: First, the upper lid is everted in the usual way, and the boric acid is thickly sprinkled on the palpebral conjunctiva. The powder is then rubbed into the conjunctiva with the end of the index finger for five or ten seconds, after which the remaining boric acid may be washed away with a soft brush dipped in "lead lotion," or if there is not much discomfort it may be allowed to remain. The lower lid is then treated in the same manner. In some cases the first few applications cause pain, but after one or two applications tolerance is established. In the earlier applications pain may be prevented by instilling cocaine solution. The procedure may be repeated daily or on alternate days. The condition of the conjunctiva after two or three applications is that of healthy reaction. Dr. Beaumont then reports three cases of trachoma in which this method of treatment gave excellent results.

The Uses of Exalgin.—According to the Paris correspondent of the *Lancet*, M. Desnos has recently undertaken a series of researches upon the action of exalgin. He finds that its influence upon high temperatures is very slight, while as an anodyne its effects are marked. When amounts of from 7½ to 12 grains were given a sensation of vertigo was produced, and sweating, often profuse, was observed in many instances. The sweating was not infrequently localized or most marked over the seat of the pain for which the drug was given. Doses of 12 grains often produced very slight cyanosis. Generally, the drug was well borne by the digestive organs, and eruptions rarely occurred. The urine was usually decreased in amount, and always contained a considerable quantity of exalgin. To relieve pain a dose of 3½ grains will sometimes be sufficient, but 6 grains is an average dose. Twenty-one grains may be given in twenty-four hours in divided doses of 3 grains each. M. Desnos used the drug in various forms of neuralgia, renal colic, and in the lightning pains of tabes. The good effect in intercostal neuralgia was only slight, but in other varieties, including sciatic, and in the pains of tabes the relief was great. It was also of service in the one case of renal colic in which it was used.

An Epidemic of Sore-throat and Erysipelas Due to Infection by Milk.—In the *Glasgow Medical Journal*, October, 1890, is reported an epidemic of sore-throat and erysipelas occurring only in families that were supplied with milk from a certain farm. About eighty cases were observed. The most striking symptom was an intense inflammation of the fauces resembling erysipelas of the mucous membrane. In some cases true erysipelas of the skin developed. In two of the patients, who drank large quantities of the milk, there was a membranous exudate on the lips and tongue, but none on the tonsils or in the pharynx. The temperature was high (102° to 105°) during the first few days of the attack in every case. Convalescence was marked by extreme prostration. Paralysis was not observed and albuminuria was noted in only two cases. Three deaths occurred, all in infants under two years of age.

Unfortunately, no bacterial examinations of the milk were made, nor was there any search for ptomaïnes, but the connection between the epidemic and the milk-supply seems pretty clearly established.

Injection for Gonorrhœa.—The following prescription is quoted by the *Deutsche medicinische Wochenschrift*:

R.—Antipyrine		1 drachm.
Sulphate of zinc		7 grains.
Cherry-laurel water, Rose water	of each	2½ ounces.

Use as an injection.

An Ointment for Prurigo.—According to *La Semaine Médicale*, the following prescription is useful in the treatment of prurigo:

R.—Resorcin		35 grains.
Precipitated sulphur		5 drachms.
Carbolic acid, Salicylic acid	of each	7 grains.
Chloral		20 "
Vaseline		1½ ounces.

Use externally.

The Medical News.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author.

SATURDAY, NOVEMBER 8, 1890.

POISONING FROM THE SURGICAL USE OF IODOFORM.

ALTHOUGH discovered in the latter part of the first quarter of the present century, iodoform was not very extensively used until about ten years ago, when Mosetig von Moorhof made known its virtues for surgical purposes. In late years its employment in the dressing of wounds, as an application to ulcers, and as an agent for the destruction of tubercle as met with in surgical diseases, has been very general. As is well known, the forms in which it is now used are: pure, as a powder; incorporated with gauze; combined with collodion; dissolved in ether, and in emulsion in glycerin or in oil. For injecting into cold abscesses, after their evacuation by aspiration, Verneuil is authority for the choice of the ethereal solution, the strength being five per cent., while the name of Mikulicz is associated with the ten-per-cent. glycerin emulsion, and Bruns has recommended a solution in olive oil of an equal strength. For this latter purpose, the treatment of cold abscesses, iodoform has proved itself a very valuable remedy.

It is, of course, chiefly due to its antiseptic properties, which are universally admitted, even though distinctly limited, that the drug has found favor. That it is not a substance to be applied with an unsparing hand, however, has been known for years; occasional reports of cases of poisoning caused by its use warning us that it must not be looked upon as wholly innocuous.

One of these unfortunate occurrences is reported by M. L. BAROIS (*Archives de Médecine et de Pharmacie Militaires*, No. 8, 1890). In this instance death was caused by the injection of about 55 grammes of a five-per-cent. ethereal solution into the cavity of a large cold abscess under the greater pectoral muscle of the left side. The amount of iodoform used was about 2.75 grammes. Symptoms of ether-narcosis immediately followed the injection, and were succeeded by the toxic effects of iodoform. The symptoms were chiefly cerebral, and continued for nine days, when death in coma supervened.

In addition to an excellent description of his observations in this case, the writer includes a review of the literature of the toxicology of iodoform, his investigation having yielded the discovery of forty-two reported cases, a table of which he presents. From his study of the question Barois found that the symptoms of poisoning make their appearance early and suddenly in the severe cases, and consist of mental depression succeeded by excitement, restlessness, and other signs resembling those of acute meningitis, such as hallucinations, etc. Periods of remission may occur, and gradual cure follow; or abundant sweats, a somewhat elevated temperature, dyspnœa, and a feeble pulse may develop, and a fatal termination is then to be expected. In the young and vigorous the latter are the symptoms which are most likely to occur, while in the old and in those of feeble constitution, the onset as well as the nature of the symptoms will be less intense, comprising anorexia and vomiting, mental depression, weakness of the limbs, and but slight disturbance of the temperature. In this latter type death has seldom been the result.

Search for the explanation of these calamitous effects of iodoform led to the institution of a number of experiments, and the results first obtained by Mundy and Mosetig von Moorhof at the bedside, and by MacKendrick and Binz in the laboratory, pointed to certain narcotic properties possessed by the drug. Hogyes, however, showed that in order to induce toxic symptoms in man it would be necessary to employ a very large quantity, 84 grammes, of the agent if the above theory were correct. A glance at the table given by Barois shows that disaster resulted from the application of much smaller quan-

tities in all but five of the cases. From further experiments conducted by MacKendrick, Binz, and Hogyes, the following conclusions were reached: "First, iodoform given by subcutaneous injection is slowly decomposed in the fat: second, from a solution of iodoform in oil or fat, iodine is separated after several hours; third, the iodine set free forms albuminous clots, which disappear without leaving any traces in the tissues."

These results have since been confirmed, and both clinical and post-mortem evidence harmonize with them. It is iodine, then, which lies at the bottom of the mischief. Iodoform, readily decomposed in the presence of the subcutaneous fat of a wound, or in the tissues surrounding an abscess, liberates iodine, which, in the form of an unstable albuminoid compound, is taken up into the circulation and conveyed to the various organs of the economy, producing in them certain marked changes, as proved by the autopsies of the fatal cases. Before death evidence of its absorption is furnished by the excretion of iodine in the urine in the form of iodide of potassium. The pathological changes are a fatty condition of the liver, the kidneys, and the heart and other muscles, together with less significant lesions. The early appearance and the character of the cerebral symptoms in all the cases would lead us to expect more or less pronounced cerebral lesions to be found on inspection. Nothing more, however, is noted than "hyperæmia of the meninges and some arterial atheromatous lesions."

Two questions which are here pertinent are: First, how much iodoform, locally exhibited, is capable of producing toxic results? Second, in what form may it be applied with the greatest impunity?

The answer to the first of these, according to Barois, cannot be determined. In his fatal case the amount was but 2.75 grammes, while other observers have used much greater quantities without bad effects. Verneuil is said to be of the opinion that poisoning need not be feared when not more than 2.5 grammes are applied. In reply to the second question it may be stated that when incorporated with gauze iodoform may be used with greater safety than in glycerin, oil, or ether.

A glance at the table of the cases of fatal intoxication impresses one with the fact that a notable number of accidents followed operations upon the same anatomical region. Of the forty-two cases thirteen occurred after operations for cancer of the breast, and one after opening an axillary abscess. Adding to these Barois's case we have a total of forty-three cases, in fourteen of which the poisoning resulted from the application of iodoform to the costo-mammary region.

The prevention of iodoform-poisoning will be best insured, first, by limiting the amount applied to that which has been shown to be the minimum fatal dose; secondly, by the exercise of especial care in patients suffering from certain classes of maladies, which, we may assume from our knowledge of the symptoms of iodoform-poisoning, would be easily influenced by the drug, such patients being those affected with cardiac, nervous, or renal diseases; thirdly, by being particularly cautious in the use of the agent in that region in which it has been shown to be peculiarly dangerous—the costo-mammary region.

As to the treatment to be pursued in these accidents, it is recommended that in addition to the removal of the cause—the suspension of the application—if possible, some unirritating alkali should be locally used, to neutralize at once the iodine set free, and prevent its entering into albuminoid combination; also that the alkalinity of the blood should be increased by the internal exhibition of alkaline salts, Vichy water, or bromide of potassium.

In conclusion, we allude to the fact that in the forty-three fatal cases above referred to, but a single one occurred in the practice of American surgeons. This case, reported in 1881, by Dr. Sands, of New York, was one in which colotomy had been performed for rectal cancer, the dressing consisting of powdered iodoform and iodoform-gauze, the amount of the drug used being 6 grammes.

Whatever its virtues, then, iodoform must be recognized as a positively dangerous substance when applied too liberally, and surgeons will best cope with the baneful results which it is capable of producing by putting into practice the principle of "an ounce of prevention," and restricting the amounts employed well within the limit of safety.

THE ETIOLOGY OF SQUAMOUS EPITHELIOMA.

The occurrence of carcinomatous changes in chronic ulcerations of epithelial surfaces has long been appropriated by the adherents of Virchow's hypothesis of tumor etiology as direct evidence in favor of the correctness of the view of an irritative origin of such growths; and not infrequently such

occurrences are offered as directly opposing the suggestions of Cohnheim as to the embryonal origin of neoplasms. In an article in the *North American Practitioner*, September, 1890, Dr. Van Hook, after describing the clinical aspects of two cases of flat-celled carcinoma, arising, one in a chronic ulcer of the leg, and the other in the skin near a fistulous opening leading to an osteal necrosis of many years' standing, briefly reviews the pathology of such growths, calling attention to the paper of Boegehold, published in *Virchow's Archives*, in 1882. In the latter paper the writer, according to Van Hook, accepts as conclusive the well-worn theory of Virchow, setting aside Cohnheim's views as valueless for two reasons: "First, because these carcinomata arise in tissues of new origin, where no misplaced embryonal cells could exist; second, because the regenerative activity is here exhausted, whereas the Cohnheim theory demands an increase in this activity."

There are, however, certain suggestions arising from a study of the minute relations of the growth of these neoplasms to normal organization which are worthy of consideration, and which accentuate the incompleteness of the views of Virchow as explanatory of the growth of tumors. That the primary cause of the original wound was of a mechanical or chemical nature, can, in the majority of instances, be clearly demonstrated; but in attempting to explain how that irritation may induce the normal regenerative process to assume a pseudo-formative character, the mechanical theory is wholly inadequate. That any given irritation may excite cellular formation for the purpose of regeneration, or for the exclusion of the source of irritation, is the simple statement of a fact long observed; for the understanding of the manner of transformation of this normal formation into tumor formation further consideration must be invoked.

In the formation of new tissues in the healing of wounds of epithelial surfaces there may be uniformly observed an apparently undue proliferation of the epithelial cells. Near the margin of an ulcer or along the edges of a wound where the proliferation is most marked, minute examination at an early stage usually reveals a distinct line of separation between the forming epithelial cells above and the embryonal connective tissue in the deeper portions of the part; later, however, as if to gain a firmer hold upon the underlying structures, the epithelial layer is prone to send into the young connective tissue beneath, long, slender, branching prolongations, which persist for a considerable period after organization is complete. In this process of organization the new tissues are essentially embryonal in nature, and the process is entirely analogous if not identical, in the formation of the cells, in the character of the vascular supply and the mode of growth, to embryonic generation. Nor can the second objection of Boegehold be maintained, since the regenerative energy of the epithelial tissues, at least, is frequently evident even to superficial observation in these chronic ulcers by the heaped-up, irregular masses of epithelium distributed chiefly along the borders of the sores.

In the process of cicatrization it may be readily conceived that by the contraction of the newly-formed connective tissue, portions of these epithelial prolongations, retaining their vegetable energy and the functions of the dermal layer, may be entirely separated from the normal epithelium above. These islets of displaced growing epithelium, persisting in their penetrating tendency and in their squamous character, constitute the point of departure from the normal epithelial covering to the tumor of epitheliomatous type; and the presence of such actively-vegetating foreign tissue may give rise to the irritation necessary to the long continuance of the inflammation characterizing these chronic ulcers.

Viewed in this light, instead of militating against the proposition of Cohnheim that tumors are essentially accidents of embryonal procedence, the growth of these epitheliomata distinctly favors the verity of such an hypothesis. There exists in these cases a true displacement of cells of an embryonal nature by a species of invagination, which, although occurring in the adult, bears close analogy to the invaginations in the blastodermic layers in embryonic organization. While in many cases of chronic ulceration there seems to be a depression of the regenerative energy of the connective tissues, there is not, as Boegehold would suggest, any lack in the vegetative power of the epithelial elements. On the contrary, epithelial proliferation is as a rule excessive, as shown by the rapid closing of wounds in healing by first intention, and by the masses of epithelial tissue along the margins of an old ulcer; and it is not improbable that there should be regarded as an element in the tumor-growth in these cases, a failure of the normal resistance of tissue to tissue, connective tissue to epithelial, as proposed by Thiersch in relation to the epitheliomata of old age.

REVIEWS.

The Science and Art of Obstetrics. By Theophilus Parvin, M.D., LL.D. Second edition revised and enlarged. Philadelphia: Lea Brothers & Co., 1890.

This excellent text-book has already found its way into the library of so many practitioners and is so generally used by students that the second edition needs but few words from the reviewer. Among the additions noted is Hegar's sign of pregnancy, which is described without comment and with which the author seems to have had no experience. The method of treating eclampsia by the hypodermic administration of morphine is referred to as being considerably used, but here, too, our author refrains from expressing his opinion. Of antisepsis in labor the author, naturally, writes in more positive terms than in the first edition, and clearly prefers creolin to either corrosive sublimate or carbolic acid.

Were we asked to state the chief fault of Dr. Parvin's treatise we would say that the author shows too distinctly his respect for authorities and that he expresses his own opinions too infrequently. For instance, in the section on the resuscitation of asphyxiated infants, four methods of performing artificial respiration are described, and the reader can only infer that Dr. Parvin prefers Schultz's method. Some, however, may deny that this absolute freedom from dogmatism is a fault, and unquestionably it possesses the advantage of requiring students to form their own opinions, besides being discouraging to what has been aptly termed "mental laziness."

The most valuable features of the book are the lucidity of the author's descriptions and a peculiar charm of style which tempts one to read page after page when, perhaps, the intention was merely to look up some forgotten fact. As a whole, we believe that Dr. Parvin's treatise is the best book on obstetrics for undergraduate students that has yet appeared, but that for men in active practice there are one or two other books equally good.

SOCIETY PROCEEDINGS.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, October 7, 1890.

The President, Landon Carter Gray, M.D., in the Chair.

Dr. W. B. Pritchard presented the brain of a patient who died from tuberculous meningitis. When first seen by the speaker, the patient was suffering from obstinate insomnia and headache. A few days subsequently the thermometer showed some elevation of temperature, but this did not exceed 103° until shortly before death. The mental disturbances were very marked from the beginning. There was complete loss of memory, right-sided ptosis, difficulty, and finally loss, of speech, and the rapid development of symptoms of complete bulbar paralysis. The immediate cause of death was apparently involvement of the vagus. There was decided right hemiparesis. A very offensive purulent discharge from the nose was present, and continued until the patient's death. The autopsy revealed over the right parietal bone a cavity with about the circumference of a dime, the necrosis being presumably tuberculous in character. Over the right eye were a linear scar and a depressed fracture, but apparently the brain was not affected by the fracture. At the base of the brain a thick tenacious material was found. The medulla, pons, crura, and cranial nerves were involved, and the dura over the convexity of both hemispheres was covered with an apparently tuberculous deposit.

Dr. William A. Hammond read a paper entitled,

CAN WE DIAGNOSE HYPERÆMIA OR ANÆMIA OF THE CORD AND BRAIN?

The reader said that for many years he had been familiar with a group of symptoms which, from their etiology and general characteristics, are indicative of cerebral disturbance. About twenty-five years ago, after considerable observation and many experiments performed upon the lower animals and upon man, he came to the conclusion that these symptoms are the result of an increased amount of blood in the brain. The theory which he had advanced was, that natural sleep was due to a comparatively anæmic condition of the brain, normal wakefulness to an excess of intracranial blood. Hence, persistent insomnia is necessarily a pathognomonic symptom of cerebral hyperæmia. If this symptom is associated with pain in the head, a feeling of distention, heat, vertigo, and hallucinations, and is aggravated by the recumbent posture and by drugs which increase the amount of blood in the brain, there can be no doubt of the presence of cerebral congestion. The reader had made many experiments with ergot, and is convinced of its efficacy in diminishing the quantity of intracranial blood.

In conclusion, he said that if a patient came to him suffering from insomnia, pain in the head, vertigo, hallucinations, suffusion of the face, cephalic heat, &c., and if the symptoms disappeared under the influence of such remedies as the bromides, ergot, ice and douches of cold water to the nape of the neck, cupping in the same locality, nasal bloodletting, or spontaneous hæmorrhage, he thought it evident that the patient was suffering from cerebral hyperæmia.

In discussion, Dr. M. Allen Starr said that while he did not oppose Dr. Hammond's views, still his convictions at present were those expressed by Dr. Gray in a paper recently read before the Neurological Society. The symptoms explained by the assumed existence of cerebral hyperæmia can also be produced by other causes. Wakefulness, for example, is often noticed in individuals who are very much exhausted, as in puerperal women after a severe hæmorrhage. He has also observed it in patients who were anæmic. Therefore, that wakefulness necessarily indicates a hyperæmic brain is a theory which is hardly tenable. Certainly hyperæmia of the brain may, under certain conditions, be diagnosed, but it is an open question whether this can be done when only wakefulness is present.

As to drugs, he had been surprised to hear Dr. A. H. Smith and Dr. Peabody state at a meeting of the Practitioners' Society last winter, that they had been treating

cases of supposed hyperæmia of the brain with nitroglycerin and nitrite of amyl. These drugs, which are supposed to increase the amount of blood in the brain, were given upon the hypothesis that they dilated the entire arterial system of the body, and that the brain would thereby, to a certain extent, be relieved of blood. The reasoning at least appeared sound.

Dr. J. Leonard Corning thought that this reasoning was not scientific. If a patient complained of headache, and had a congested face and a pulse of high tension, and if the symptoms could be promptly relieved by pressure upon the carotids or jugulars, or by bandaging the legs, which should be assumed, congestion or anæmia of the brain? The speaker thought, congestion. If quinine or alcohol aggravated the symptoms, it would be certainly concluded that the trouble was congestion.

Dr. Gray then enumerated the conditions in which the symptoms described by Dr. Hammond might be found. Insomnia, he said, is common enough in mental diseases, worry, overwork, and constipation, and in many conditions in which there is nothing to show that there is hyperæmia of the brain. In the early stages of intracranial syphilis there is a condition somewhat of the nature of hyperæmia. But in Bright's disease, in which also there are hyperæmia and congestion, there is stupor. In some cases of insomnia it is possible to find a certain train of symptoms which would lead to the assumption of existing anæmia, and in others the symptoms would indicate hyperæmia. Experiments have recently been made on the brains of animals, the reports of which differ from those of other experimenters as to the cause of the increased volume of the brain during the waking period. It is an open question whether this increase is not due to cellular activity which increases the amount blood.

As to the association of sleeplessness with the recumbent posture, of course the extended observations of the author of the paper deserve due consideration, but so also do the more limited observations of the speaker, who has not been able to verify the association.

The question is not as to the existence of cerebral hyperæmia or anæmia, but as to whether it can be clinically diagnosed. Flushed face may be dependent upon chorea, general paresis, or injury of the brain, and it is in such cases impossible to say whether the symptom was brought on by hyperæmia alone. The feeling of oppression and sense of fulness in the head are sometimes associated with errors of refraction, insufficiency of the ocular muscles, changes of climate, errors of diet, &c. To assume that in all these conditions there is hyperæmia of the brain, is assuming more than can be proved. It has not been demonstrated by any pathologist whether an increased amount of blood in the cellular tissue of the brain can exist without causing disease of the surrounding parts. It is strange that Dr. Hammond, after five months' study of the subject, cited no autopsies in confirmation of his theory.

Dr. C. L. Dana said that it is now generally admitted that there is such a condition as cerebral hyperæmia, and that it can be recognized in its acute forms. Such a state might be produced by drugs, certain neuroses, and trauma. The question is, What is the condition at the base of that functional disorder which has gone by the name of cerebral neurasthenia? Acute and chronic hyperæmia of the brain are conditions admitted to exist, but it is preferable to say "functional cerebral neuroses" or "psychoses" if the hyperæmia is a secondary process, which seems the inevitable conclusion if such cases are closely observed.

Many patients among the neurasthenics have symptoms of congestion of the brain; others of this class do not present the symptoms of typical cerebral hyperæmia. The hyperæmia of the brain is secondary to some disorder of the vaso-motor nerves, or to some functional condition involving the whole nervous system.

To state that sleep is produced by anæmia, and wakefulness by the return of the normal amount of blood to the head, is, the speaker thought, in the light of modern neurological studies, a theory unworthy of further investigation.

Dr. Hammond thought that his statements were not disproved. When Dr. Dana said that the neurologists of to-day ignored the theory of the physiological changes during sleep—a theory which the speaker might claim as his own—he thought that Dr. Dana was in error. He had stated that innumerable causes of headache existed, and it is only when it is associated with flushed face and vertigo, and when it is increased by a dependent position, that the diagnosis is certain.

CORRESPONDENCE.

MEDICAL LAW AND EXAMINATIONS IN MONTANA.

To the Editor of The Medical News,

Sir: Prior to the passage of House Bill No. 6, by the Sixteenth Legislative Assembly of Montana, in March, 1889, the restrictions regarding the requirements for the practice of medicine in Montana were few, and carelessly complied with. The Bill mentioned above is "An act to regulate the Practice of Medicine in the Territory of Montana, and to provide for the examination and issuing of certificates to persons desirous of practising the same, and for the punishment of persons violating the provisions of the Act."

There has been considerable consternation in the profession in Montana since this law went into effect, and a number of lawsuits have resulted. When the Act passed there were many undergraduates practising in the Territory, and the new law required all of these who had not been in continuous practice here for at least ten years, to appear before the Medical Board for examination. Those holding diplomas of reputable colleges were granted license to practise. The greatest "kick" is by physicians who came to Montana after the law went into effect, and who had been in practice in other States, and possessed good diplomas—yet were required to submit to an examination by the Board. But after becoming familiar with the manner in which the people have been preyed upon by the unscrupulous "quacks," the intelligent physician at once sees the necessity for such a law—both to the laity and the profession.

Section 1 of the law says: "The Governor, with the advice and consent of the Council, shall appoint seven learned and skilled physicians—who shall have been

residents of the Territory of Montana for not less than two years preceding their appointment—not more than two of whom shall be from the same county—who shall constitute the Board of Examiners for the purposes of this Act." The Board consists of six regulars and one homœopath, who is the treasurer of the Board. Meetings for the examination of applicants and granting certificates are held on the first Tuesday of April and of October of each year, four members of the Board constituting a quorum.

The first meeting of the Board was held in Helena, October 7th, five members and about twenty-five applicants for examination and certificates being present. The members of the Board decided that each applicant should make affidavit in writing, of his age, the time spent in the study of medicine, the college by which he was graduated, and the date of his diploma. The examination was oral, each applicant going before each member of the Board. The questions asked, so far as your correspondent could learn, were straightforward and reasonable, strictly confined to the branches required by law, and well calculated to test an applicant's medical ability—"catch" questions being avoided.

For the benefit of those who are interested, I will give a *few* questions that were asked which may serve to remove the undue prejudice that exists against the law, and the persons appointed to execute it In Anatomy, the following questions were asked: "What is anatomy? How many cavities in the heart? Where are the semilunar, the tricuspid, and the mitral valves? Describe the vomer, and tell where it is situated. What is the name of the principal artery supplying the stomach? Give the origin and insertion of the gastrocnemius. Name the coverings of the brain, and the situation of each. Where is the seminal vesicle? Name the different divisions of the alimentary canal."

In Physiology, the examination was as follows: "Describe the circulation of the blood. How many kinds of circulation are there? What is the function of the liver, and through what channel does the liver get its blood-supply? What are the principal constituents of the gastric juice? Name the five digestive fluids."

In Materia Medica: "Give the physiological action of aconite, the directions for its use, and the dose. What is opium? Which is the more powerful, hydrargyri chloridum mite or hydrargyri chloridum corrosivum? Give the dose of each. How much antipyrine would you give at a dose, and how often would you repeat it? What is the dose of phenacetin?"

In Practice of Medicine: "What is pneumonia? Name the different stages, and give the treatment of each. How would you treat sick-headache? Name the principal means used in examining for disease of the chest."

In Chemistry and Toxicology: "For what purpose is 'Fehling's solution' used? How would you recognize and treat a case of strychnine-poisoning? Give the symptoms and treatment of a case of arsenic-poisoning. In what way does a fatal dose of the mineral acids cause death?"

In Surgery, some of the questions were: "How would you treat 'Colles's fracture'? What do we understand by antisepsis? Name some of the indications for amputation. What is skin-grafting? How would you treat an extra-capsular fracture of the neck of the femur?"

In Obstetrics: "How would you treat post-partum hæmorrhage? What are the indications for the use of forceps? How would you control convulsions occurring in the course of labor?"

Diseases of the Eye and Ear: "What is iritis, and what is the proper treatment? What is chemosis? How would you treat acute catarrhal conjunctivitis? How would you treat purulent conjunctivitis? Give the treatment for ulcer of the cornea. What is otorrhœa? Give the proper treatment of chronic discharges of the ear?"

Diseases of Children: "How would you differentiate measles from scarlet fever? Can you name an eruptive disease in which the temperature falls to normal when the eruption appears?"

Diseases of Women: "What is metritis? What is cervical endometritis? Give the treatment for the same. What do you understand ovariotomy to be? Name some of the tumors which develop in the female generative organs. How would you treat pelvic abscess?"

No two of the applicants were asked exactly the same questions, and the above questions are only some of those asked the writer and two other applicants. Three applicants were refused certificates, because they declined to submit to the examination and because they had not complied with the law in having attended three courses of lectures of at least four months each, and in being the possessor of a diploma from a reputable medical college.

Section 4 of the Act contains this clause: "In all cases of refusal or revocation the applicant, if he or she feels aggrieved, may appeal to the district court of the county where such applicant may have applied for a certificate." Some rejected applicants are taking advantage of this, and, of course, giving the Board unnecessary trouble.

The fee for the examination and certificate is fifteen dollars, and physicians coming to the State at any time may make application to any member of the Board for a certificate to practise, by presenting a reputable diploma and paying the fee, whereupon he will be granted a temporary certificate, good until the next meeting of the Board, at which time he must appear for examination. A few, defiantly refuse to comply with these provisions, and, against all such, the Board will be compelled to take legal proceedings.

Of the applicants, three were homœopaths and the remainder regulars. One member of the Board remarked that in no instance had he known an applicant to be asked whether he was a regular or irregular.

To my brother practitioners who are contemplating going before the Board and passing through the ordeal of an examination, I would say that my opinion of the Board is entirely different from that which I entertained previously to the last meeting, and that the examinations are perfectly fair. G. T. MCCULLOUGH, M.D.

MISSOULA, MONTANA.

RUSH MEDICAL COLLEGE AND THE NORTHWESTERN UNIVERSITY.

To the Editor of THE MEDICAL NEWS,

SIR: Your Chicago correspondent made some very misleading statements in his letter published in THE

Medical News of October 11th. Professor Roberts never was connected with the Northwestern University, but he is the President of the Lake Forest University, and to that latter institution his figures referred. The Northwestern University never had or desired any connection with Rush Medical College. A short time ago, after the latter college had made for itself a reputation, and had a large patronage, Lake Forest University made advances to it and secured a union of interests. Lake Forest is twenty-eight miles north of Chicago, on Lake Michigan. The Northwestern University is located at Evanston, also on Lake Michigan. The main campus is just twelve miles from the Court House in Chicago. It has an endowment of over $3,000,000, and has enrolled this year over 2000 students. Dr. Rogers, who succeeded Judge Cooley as Dean of the Law School of Michigan University, recently accepted the presidency of the Northwestern University. This University has in Evanston, the College of Liberal Arts, the Woman's College, School of Oratory, Conservatory of Music, Preparatory Department, and three theological schools. In Chicago are located the schools of medicine, pharmacy, dentistry, and law. At Evanston, and in the care of the University, is the large Dearborn telescope. For the use of scientific students in Evanston there is a large hall, with ample chemical and physical laboratories. In the College of Liberal Arts there is a course designed, whether wisely or not, especially for those intending to study medicine.

The medical department of the University is known among our profession as the Chicago Medical College, of which N. S. Davis, M.D., LL.D., is the Dean. This was the first medical school in the United States that established a graded course of three years, obliging students to pass examinations on the first year's work before taking a second. It was also one of the first medical schools in this country to insist upon a preliminary examination or a diploma from a literary school. Every person before graduation must have been a member of a clinical class of from four to eight, or perhaps ten, who receive special training in the diagnosis of such cases as are met with in office practice—this in addition to the general hospital and college clinics. The result is that a large proportion of the students are weeded out before the diplomas are granted.

A new building is to be erected by the Northwestern University on the south side of the city, for the schools of pharmacy and dentistry and for laboratories for the medical school. Very respectfully,

Henry B. Hemenway, M.D.

Evanston, Ills., October 15, 1890.

NEWS ITEMS.

Obituary.—Dr. Henry Jacob Bigelow died at the age of seventy years, at his home at Oak Hill, Newton, Mass., shortly before noon on October 30th, and it may be truly said that in his death Boston has lost a surgeon who in his ability, originality, and ingenuity of invention, has not been equalled in the past or present.

As long ago as 1844 he began to publish a number of surgical works which soon gave him a world-wide reputation, and an essay of his on "Orthopædic Surgery" obtained the Boylston Prize of Harvard University in 1844. He invented what is known as Bigelow's operation of lithotrity, the value of which is universally recognized. The French Academy of Medicine awarded him a prize for the operation in 1882, although the medical profession both in this country and abroad had long before recognized its value and resorted to it. Harvard University conferred the degree of LL.D. upon Dr. Bigelow in 1882, and he was made Emeritus Professor of Surgery in Harvard Medical School.

He retired from the practice of medicine in 1886. For a long period Dr. Bigelow was a sufferer from gastric and hepatic disease and his death was not unexpected by his friends.

The Recent Medical Examination in New Jersey.—Among the answers given to the New Jersey Medical Examining Board by applicants for license to practise were the following:

Question. Write a prescription for acute diarrhœa in a child ten years old.

Answer.

"℞.—Tinctura opii . . . 1 drachm.
" catechu . . 5 drachms.
" kino . . . 2 drachms.—M.

"Take a teaspoonful every three hours."

Q. Name three cathartics.

A. "Compound cathartic pills, hydrar. cum creta, calomel."

Q. Describe a case of cirrhosis of the liver.

A. "Pain in the left side over the liver toward the back. . . ."

Q. Describe briefly how you would investigate a surgical case, and by what method you would write a history of such a case.

A. "I should investigate a surgical case under antiseptic precautions whenever practicable, and should write a history of such a case by the antiseptic system of surgery."

Q. What is an acute abscess?

A. "A deep-seated, burrowing sore."

Q. Describe the operation for tying the external iliac artery.

A. "Etherize the patient, perform everything under antiseptic care, make an incision through the skin, fascia and connective tissue."

Q. Supposing in a case of retention of urine from an enlarged prostate, you could not succeed in passing the catheter by the natural passage, what proceeding would you adopt?

A. "I should at once give diaphoretics, hydragogue cathartics, and apply warm poultices to the abdomen over the bladder. If all this should fail I should perform the operation of laparotomy."

Q. Describe the diaphragm.

A. "The diaphragm is perforated by several orifices. The œsophageal, aortic, venæ cavæ, and pharyngeal orifices."

Q. Describe the circle of Willis.

A. "In the fœtal circulation the blood pouring directly through the heart instead of the lungs forms the circle of Willis."

Q. What is the difference between calomel and corrosive sublimate?

A. "Calomel contains but few corrosive and antiseptic properties. Corrosive chloride of mercury is a powerful corrosive agent and is a strong antiseptic."

Q. In what does human blood differ from that of a frog?

A. "The corpuscles in human blood contain a nucleus, and corpuscles in the blood of a frog contain no nucleus."

Q. Give the condition of the mucous membrane of the stomach in chronic inflammation thereof.

A. "In chronic inflammation of the stomach the mucous membrane presents, on inspection, a bright-red appearance. Large spots of mucous membrane is destroyed. The bloodvessels are congested. There is thickening of the mucous folds."

Q. Give the treatment of acute conjunctivitis.

A. "Apply eye-water every two hours. . . ."

Q. What are the operations for cataract?

A. "The operation for cataract consists in removing the cataract with a knife, which is done by introducing it into the eye back of the crystalline lens and removing that portion which is affected."

A Mohammedan Female Physician.—Dr. Razie Koutlairoff-Hanum, a young Mohammedan woman, who was born in the Crimea, recently passed a creditable examination as physician and surgeon at Odessa, and now enjoys the distinction of being the first woman of her creed to engage in the practice of medicine as understood by western nations.

A Hospital in Central Africa.—As an instance of the civilizing work now being carried on in the Congo Free State, may be mentioned the Bangala-station hospital, in the upper Congo basin, a little less than a thousand miles from the Atlantic coast. It was erected for the employés of the station, and contains forty beds, besides rooms for convalescent patients.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM OCTOBER 28 TO NOVEMBER 3, 1890.

ARTHUR, WILLIAM H., *Captain and Assistant Surgeon.*—Is relieved from duty at Fort Bayard, New Mexico, and will report in person to the commanding officer Fort Grant, Arizona Territory, for duty at that post, relieving William B. Banister, First Lieutenant and Assistant Surgeon. Lieutenant Banister, on being relieved by Captain Arthur, will repair to this city, and report for duty to the commanding officer Washington Barracks, District of Columbia.—Par. 12, *S. O. 254, A. G. O., Washington, D. C.*, October 30, 1890.

WAKEMAN, WILLIAM J., *Captain and Assistant Surgeon.*—Is relieved from duty at Fort Bidwell, California, to take effect on the final discontinuance of that post, and will then report in person to the commanding officer Fort Huachuca, Arizona Territory, for duty at that station.—Par. 12, *S. O. 254, A. G. O.*, October 30, 1890.

WALES, PHILIP G., *First Lieutenant and Assistant Surgeon.*—Is relieved from station and further duty at Fort Huachuca, Arizona Territory, and assigned to duty at San Carlos, Arizona Territory, where he is now temporarily serving.—Par. 13, *S. O. 254, A. G. O.*, October 30, 1890.

So much of Par. 2, S. O. 208, A. G. O., September 5, 1890, as directed NATHAN S. JARVIS, *First Lieutenant and Assistant Surgeon*, to report for duty at San Carlos, Arizona Territory, is revoked. On the expiration of his present sick-leave of absence, Lieutenant Jarvis will report in person to the commanding officer Fort Bayard, New Mexico, for duty at that station.—Par. 13, *S. O. 254, A. G. O.*, October 30, 1890.

CONWAY, STEVENS G., *Surgeon.*—Is granted leave of absence for one month, with permission to apply for an extension of fifteen days, to take effect upon the arrival of Acting Assistant Surgeon A. P. Frick at Fort Marcy.—Par. 2, *S. O. 112, Department of Arizona, Los Angeles, Cal.*, October 24, 1890.

EOIE, GUY L., *Captain and Assistant Surgeon* (Fort Douglas, Utah).—Is granted leave of absence for one month, on surgeon's certificate of disability.—*S. O. 80, Headquarters Department of the Platte, Omaha, Nebraska*, October 27, 1890.

By direction of the Secretary of War, the leave of absence granted CHARLES B. EWING, *Captain and Assistant Surgeon*, in S. O. 131, Department of the Missouri, September 22, 1890, is extended fourteen days.—*S. O. 250, A. G. O.*, October 25, 1890.

By direction of the Secretary of War, the following changes in the stations and duties of officers of the Medical Department are ordered:

WOODRUFF, CHARLES E., *First Lieutenant and Assistant Surgeon.*—Is relieved from duty at Fort Gibson, California, and will report in person to the commanding officer Fort Missoula, Montana, for duty at that post, relieving Calvin De Witt, Major and Surgeon. Major De Witt, upon being so relieved, will report in person to the commanding officer Fort Hancock, Texas, for duty at that post.—Par. 6, *S. O. 249, A. G. O., Washington, D. C.*, October 24, 1890.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING NOVEMBER 1, 1890.

STEPHENSON, F. B., *Surgeon.*—Detached from Receiving-ship "Wabash," and wait orders.

MARTIN, H. M., *Surgeon.*—Ordered to the Receiving-ship "Wabash."

STONE, LEWIS H., *Assistant Surgeon.*—Ordered to the U. S. S. "Pinta."

ARNOLD, WILLIAM F., *Assistant Surgeon.*—Detached from the U. S. S. "Pinta," and granted two months leave.

OWENS, THOMAS, *Surgeon.*—Detached from the Coast-survey Steamer "Blake," and wait orders.

BLACKWOOD, N. J., *Assistant Surgeon.*—Ordered to the Receiving-ship "Vermont."

BOGERT, E. S., *Assistant Surgeon.*—Detached from the U. S. Receiving-ship "Vermont," and ordered to the Coast survey Steamer "Blake."

MOORE, A. M., *Surgeon.*—Detached from the U. S. S. "Kearsarge," and ordered to the Naval Hospital, Mare Island, Cal.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FROM OCTOBER 6 TO OCTOBER 25, 1890.

HUTTON, W. H. H., *Surgeon.*—Detail as Chairman of Board of Examiners revoked; ordered to Washington, D. C., for temporary duty, October 14, 1890.

WYMAN, WALTER, *Surgeon.*—To inspect quarantine stations, October 14, 1890.

LONG, W. H., *Surgeon.*—Detailed as Chairman of Board of Examiners, October 14, 1890.

SAWTELLE, H. W., *Surgeon.*—Granted leave of absence for five days, October 13, 1890.

GASSAWAY, J. M., *Surgeon.*—Granted leave of absence for thirty days, October 11, 1890.

IRWIN, FAIRFAX, *Surgeon.*—Detailed as Recorder of Board of Examiners, October 14, 1890.

AMES, R. P. M., *Passed Assistant Surgeon.*—Granted leave of absence for thirty days, October 14, 1890.

WHITE, J. H., *Passed Assistant Surgeon.*—Granted leave of absence for thirty days, October 24, 1890.

PETTUS, W. J., *Passed Assistant Surgeon.*—To proceed to Vineyard Haven, Mass., for temporary duty, October 9, 1890.

PERRY, T. B., *Assistant Surgeon.*—Ordered to examination for promotion, October 9, 1890.

KINYOUN, J. J., *Assistant Surgeon.*—Ordered to examination for promotion, October 10, 1890.

CONDICT, A. W., *Assistant Surgeon.*—To proceed to Baltimore, Md., for temporary duty, October 18, 1890.

RESIGNATION.

AMES, R. P. M., *Passed Assistant Surgeon.*—Resignation, to take effect November 15, 1890, accepted by the President, October 14, 1890.

ORIGINAL LECTURES.

THE MORBID ANATOMY OF TYPHOID FEVER.

The Annual Address,
delivered before the Philadelphia Pathological Society.

BY ARTHUR V. MEIGS, M.D.,

PHYSICIAN TO THE PENNSYLVANIA AND TO THE CHILDREN'S HOSPITALS, PHILADELPHIA.

MR. PRESIDENT AND GENTLEMEN: Permit me in the first place to express to you my deep sense of the honor which has been conferred upon me by being selected to deliver the annual oration before you on this occasion.

The conception that I have formed of what such an address before a pathological society should be, is that it should embody the results of some original investigation, or if that be impossible, should suggest some line of thought in which it would seem that research might lead to something of value.

In casting about for a subject worthy of your attention, it occurred to me that a consideration of the lesions found after death from typhoid fever might be of interest. It is not that I have very much that is new to present to you upon this subject, for both in the general treatises and in the special works upon pathology will be found an immense fund of information in regard to the various morbid conditions of the tissues and organs in this complaint. Rather is it because in the course of my professional career I have been impressed with the fact that the view seems very common among physicians that typhoid fever is a disease of the intestines alone. Clinical experience as well as pathological investigations have led me to look upon this view as an erroneous one. As I have studied the symptoms presented by my patients—epistaxis, an early symptom, often present before the abdominal conditions are pronounced, the hebetude or delirium, the subsultus, the eruption and sudamina, and the marked pulmonary conditions—I have been unable to rest contented with the view that the disease is seen in its true light when looked upon as primarily a disease of the intestines. Sometimes it has struck me that the reason the disease is commonly so considered, is because it is generally known among the laity as well as among professional men that it so often arises from drinking impure water, which is taken first into the alimentary canal, and from there starts upon its course of mischief. It would be as reasonable, however, to argue that strychnine in poisonous doses produces death by its effects upon the alimentary system because it is taken by the mouth, as that typhoid fever is truly a disease of the same system; though in each the poison commonly enters by the same avenue.

The importance of conditions other than intestinal ones in typhoid fever first forced itself upon me, so far as my recollection serves, rather from considering the disease clinically than from the grossness of the organic lesions. So much was this the case that two or three years ago I determined, as opportunities might arise, to make careful studies, both macroscopically and with the microscope, of as many of the organs and tissues as time and my ability enabled me to do.

It is the outcome of these investigations, as far as they have been made, that I want to present for your consideration. My results, of course, will be found to be far from perfect and there is room for further and almost unlimited study in the same line of thought, but so far as I shall make assertion of facts of observation I think you will find them to be true. When, however, I trespass into the fields of deduction you will, of course, do well to examine my logic and accept or deny my conclusions as the result may be.

With the object in view, then, of ascertaining whether other pathological changes besides the commonly-recognized ones in the intestines and mesenteric glands might be present, and be present perhaps with a greater or less degree of constancy, I have made careful search in some of my cases. The picture I wish to place before you cannot, I think, be better presented than by reporting somewhat in detail a case that was studied at considerable length.

There was admitted to the Pennsylvania Hospital, August 18, 1889, a man, twenty-seven years of age, who was born in America. He belonged to the laboring class, and said that he had never suffered from any previous illness except an acute attack of some kind when seven years old. He denied having indulged in excesses of any sort. Six days before admission to the hospital he ate watermelon and the next day was taken with abdominal pain; soon diarrhœa with a sense of heaviness and weakness of the legs came on. The day before coming to the hospital he had epistaxis, but he continued to work until his admission, though his appetite was poor and he had continual abdominal pain. He had also some cough and expectoration.

On admission his temperature was $103\frac{3}{5}^{\circ}$ and there was some tendency to retention of the urine. The tongue was moist and coated with a white fur, but not tremulous. There was no eruption upon the abdomen.

Physical examination gave the following results: The first sound of the heart was soft (anæmic); the lungs were everywhere filled with bronchial râles; the hepatic dulness was of the natural extent, and the splenic dulness was somewhat increased. The treatment was four grains of quinine twice daily and ten drops of dilute muriatic acid three times daily. He continued to have fever, the temperature varying generally between 101° and 104°, and after the first two days in the hospital he had diarrhœa, with from one to five stools in twenty-four hours. After a few days the tongue became dry and the pulse running, and there was much subsultus. The treatment was changed, turpentine and whiskey

being given; still later, as he continued to grow worse, spirit of chloroform and tincture of digitalis were used. No characteristic eruption appeared, but he continued to fail, the temperature rose to 106° and he became excessively nervous and died, August 27th.

At the autopsy the following conditions were found. There were many pleural adhesions, especially to the diaphragm. The lungs appeared to be much congested, being intensely dark-red and in some areas almost black, and blood freely exuded on section. The heart looked natural except that it was soft and its lining was stained very dark red. The liver was rather large and firm, but not very dark or much congested. The bile-duct was patulous. The spleen was three times the natural size, firm in texture and intensely dark red on section. The kidneys were slightly enlarged, flaccid and dark-colored on section. The small intestine throughout half its length presented many typical typhoid ulcerations of Peyer's patches, besides an unusually large number of smaller ulcers scattered generally over the inner surface. The mesenteric glands were enlarged to an unusual degree and on section some of them presented small spots of softening, the contents of which ran out, leaving cavities. The colon was congested but otherwise normal. The spinal cord presented congestion of the vessels upon its surface, especially of its lower half, where the veins were very full. The cord itself, both the surface and on section, looked natural.

Microscopical examination of sections cut from the lungs, heart, liver, spleen, kidney, ileum, mesenteric gland, and the spinal cord was made.

The most marked change presented by the lungs was that over large portions of the sections the appearance was simply that of a mass of blood. Large quantities of red corpuscles, exhibiting their characteristic outline and of a yellowish color, and unstained by carmine, with many leucocytes of varying size and appearance scattered amongst them, covered whole fields under the microscope. The blood filled the air-vesicles, bronchi, and bloodvessels, and in places there were evidences of inflammation, the tissue showing round-cell infiltration, and there being some catarrhal-exudate cells. The bronchioles and tissue for a short distance around them were inflamed, the cells of the epithelial lining having undergone proliferation, and the subepithelial tissue being infiltrated, thickened, and containing vessels filled with clotted blood. The blood-clot in one vessel of the lung-tissue was variously channelled out, new vessels being in process of formation in it, if they were not actually already formed. The heart-muscle was, in some places, in a very good state of preservation, the cross-striæ being very sharp. In other parts the fibres were homogeneous or granular-looking. It seems likely that this was due to disease and not to faulty technique, for all the tissue was preserved, prepared, stained, and mounted under precisely similar conditions, if not at the same time, and yet the same section often showed the most marked contrasts. It seems that there was some endocarditis, for the endocardium appeared to be slightly thickened, and contained more than the natural number of nuclei.

That some myocardial inflammation, independent of the state of the muscle-fibres, was present, there can be no doubt, for there was a great multiplication of the red-staining nuclei which are naturally present in the intermuscular substance. In some areas there was a great deal of brown pigment in the muscle-fibres. Hæmorrhage into the substance of the muscle appeared to have taken place at one area.

In the liver the separation of the lobules from one another showed so plainly that it recalled the appearance of the liver of the pig. This must have been due to the presence of almost structureless fibrous tissue or exudative matter between the lobules. In many places the trabeculæ could be seen, but the secreting cells had disappeared, as though by some cause the cells had been removed or destroyed, leaving the supporting framework *in situ*. In spots the tissue was broken down, looking as though the area would have been a minute abscess if life had continued longer.

The spleen was generally of a yellowish color when thin sections were examined, and the tissue did not stain well with carmine. The most marked feature was that instead of being composed of the usual small lymphoid cells, a large proportion was made up of cells of from three to five times the diameter of an ordinary lymph-cell. These in many instances were multinucleated and resembled more closely the large exudative cells so common in the lungs in inflammatory conditions than anything else.

The kidney-tissue was disorganized, as is usual in persons dying of acute diseases in which the blood is broken down, the cells being swollen and granular and often loosened from their positions. A striking feature of the picture presented was that the Malpighian tufts were nearly bare, having shed much of their epithelium.

The ileum showed the ordinary conditions of infiltration and ulceration of Peyer's glands. There was thickening, and some of the follicles had been shed, while others were in process of shedding. The thickened portion of the lymphoid tissue was, as in the spleen, largely composed of multinucleated cells several times larger than ordinary lymph-cells.

The mesenteric gland that was examined was more than an inch in its longest diameter. The cavities which were mentioned as visible to the naked eye had no specially-organized walls, there being at the periphery merely an area of active red-staining cells which shaded off into the rest of the tissue. At one area was a spot the cells of which had stained intensely red, gradually shading off to the color of the surrounding tissue; this must have been an early stage of the same condition which at a later period produced the cavities. These, it would seem, could be described only as abscesses. The condition of the cells composing the gland was parallel with that of those of the spleen and of the cells in the lymphoid portion of the ileum. Instead of being the ordinary small lymphoid cells, a great proportion of them were large multinucleated cells like those that were so abundant in the spleen.

The spinal cord presented appearances of which it is not easy to give an adequate description. That it was not healthy seems to be beyond doubt, and yet none of the changes were very gross. The postero-median (Goll's) columns in the cervical portion were in worse condition than any other portion of the tissue examined. With the naked eye it could be seen in the sections that

this portion of the cord had been stained a deeper red than the most of the tissue, and in it the nerve-fibres were not sharply outlined. The general impression was that there was too much neuroglia, which stained unduly red and seemed disposed to encroach upon the axis-cylinders. It appeared also as though the number of nuclei in the supporting tissue was increased. These appearances, of too much neuroglia, of being unusually red, and of the nerve-fibres not being as sharp in outline as natural, were present everywhere to a greater or less degree, but nowhere else to the same extent as in Goll's columns in the cervical portion. The central canal in the lumbar portion of the cord was quite widely open and the cells looked as though they had undergone proliferation. Sections were prepared from the cervical, dorsal, and lumbar regions, and were stained both with carmine and carminate of sodium, according to the method of Schultze.

This case exemplifies how extensive and grave may be the lesions in what was clinically an ordinary case of typhoid fever, in which all the usual symptoms were present except the rash. It would have been very easy for me in making the post-mortem examination to have stopped and rested satisfied after discovering the ulcerations in the ileum with enlargement of the mesenteric glands, and the usual so-called congestion of the lungs. This error I have often committed, and have thereby, I doubt not, overlooked again and again lesions as important as those of which I have given an account.

For my own part, I cannot see that we have more reason to consider typhoid fever a disease of the intestines because there seems to be invariably present a lesion of the ileum than we have to describe scarlet fever as a skin disease because one of its invariable manifestations is an eruption of the skin. Both are general diseases, and are more properly to be considered in the present state of our understanding of such things, as due to derangement of function. Amongst my records I have the notes of two cases of undoubted typhoid fever: in both of them post-mortem examinations were made, and there was found no enlargement of the mesenteric glands, it being recorded that the largest gland was not more than a quarter of an inch in diameter.

My case as described directs attention to a number of lesions that I think are both common (if not invariably present) and very important in the disease. It would have been improper for me to come before you to relate an account of one case alone and then generalize therefrom if I had made no further investigations, and it is to be understood, therefore, that any deductions I may make are the result of study in a number of cases, though in no other one was the study so extensive as in the one detailed at length.

Disease, or at least disorder, of the lungs is known to be a common accompaniment of typhoid fever, but I do not think it is ordinarily, if ever, given the prominence that belongs to it. Murchison says that he noted bronchitis in twenty-one out of one hundred cases, and that it may be one of the earliest phenomena of the disease. He says further that in a large proportion of the cases which terminate fatally within the first fourteen days death is due to bronchitis and hypostatic engorgement of the lungs. More commonly both these conditions supervene in the fourth week, and then they may lead to a fatal result. Of pneumonia, he says that he noted it in thirty out of one hundred cases.

In cases in which I have made microscopical study of the condition of the lungs—and this was typically represented in the case I have narrated in full—the appearances could hardly be classified as those either of pneumonia or bronchitis, as those terms are commonly accepted. The appearances were rather those of hæmorrhage, for as has been already stated, the air-vesicles, bronchi, and bloodvessels were filled with red corpuscles and leucocytes. In some of my specimens I have found air-vesicles filled with blood alternating with others containing fibrinous exudative material, and again catarrhal exudate cells. Commingled with these appearances were found those of inflammation of the lung-tissue—round-cell infiltration—and there were also bronchi which were much inflamed. The impression left upon the mind by all this, however, was that an early lesion was the escape of blood from the vessels. The fact that organization and the formation of bloodvessels had taken place in the clots within the very bloodvessels themselves is exceedingly interesting.

The soft heart of typhoid fever, originally described by Stokes,[1] is recognized by everyone as an almost essential feature of the disease, though its precise pathology is even yet not as thoroughly worked out as is desirable. The changes are most accurately and graphically described by Stokes, and so far as gross appearances are concerned, nothing has ever been added to our comprehension of the condition. Of course, so long ago no knowledge of the pathological histology was possible, for microscopical work was as yet of the crudest description. Stokes described what he saw as follows: "The heart is little, if at all, altered in volume. It is generally of a livid hue, but this it may have in common with other internal organs, as is often seen in fever. It feels extremely soft, especially in its left portion, and the left ventricle frequently pits on pressure. Nothing remarkable is to be found as to the pericardium or endocardium, and the valves are unaffected. The principal change is found in the muscular structure, which is often infiltrated with an adhesive, as it were, gummy secretion. The left ventricle exhibits a singular appearance, for the traces of the muscular fibres are lost, and the external layer to the depth of an eighth of an inch, converted into a homogeneous structure, in which no fibre can be found. The color of this altered portion is generally dark, and it resembles the cortical structure of the kidney. In some cases this change occurs in patches varying in depth, and from a quarter to three-quarters of an inch in breadth."

This description leaves nothing to be desired so far as the macroscopical appearances are concerned. The histological changes as I have seen them are disorganization of the muscle-fibres, which are either granular in structure and contain much brown pigment, or are homogeneous; great increase of the intermuscular nuclei, and sometimes hæmorrhage into the tissue. These

[1] It must be remembered that at the time Stokes made his observations the distinction between typhus and typhoid fevers was not yet made. This is evident from what he says in discussing the lesions in his book upon Diseases of the Heart and Aorta: "As to the intestines, we sometimes found ulcerations of the ileum, while in other cases no such lesion existed."

changes vary to almost any extent in different cases, healthy tissue alternating through the organ with diseased areas. The alterations of structure are probably not inherently irreparable, nature being capable under favorable circumstances of replacing the diseased by sound tissue. The result, therefore, the life or death of the patient, must depend, so far as the heart is concerned, upon the extent and situation of the change, complete recovery taking place in cases in which the disease has not progressed too far. The great increase of nuclei in the intermuscular tissue is a strange phenomenon, and in the present state of knowledge, somewhat inexplicable. It must be due to cell-multiplication either in the connective tissue or of the vascular tissue, the capillaries of the heart being always very rich in nuclei. Hæmorrhage into the tissue of the heart must have a most disastrous effect upon its functional activity.

The condition of the liver in some of the cases that I have seen was peculiar. The lobules were much more distinctly outlined than in the healthy state, and some evidences of degeneration and inflammatory action were present. In the *Transactions of the Pathological Society of London*, 1889, there is an article by H. Handford on "Hepatitis in Enteric Fever," in which he says: "But the most characteristic change, though so far as I have observed, not quite a constant one, is the presence of small rounded areas that stain imperfectly, that are infiltrated more or less thickly with leucocytes, and that are surrounded by a dense ring of cellular infiltration. . . . In other similar patches, which I take to be in a more advanced stage, the liver cells cannot be distinguished at all. . . . In yet a third variety there exist simply rounded aggregations of leucocytes, the smaller patches hardly distinguishable from commencing miliary tubercles, and the larger ones from the early stages of miliary abscesses." Accompanying the paper is a plate graphically representing the appearances, and both it and the description as quoted tally closely with what I myself have observed.

The spleen, everyone knows, is almost always enlarged in typhoid fever. The only thing that has struck me as at all peculiar in making microscopical examinations of that organ in typhoid fever is the appearance of the cells which I have mentioned in the description of a case, very large multinucleated cells constituting a large part of the organ. Cells of like appearance, as has already been mentioned, are very abundant in the mesenteric glands and in the glandular tissues of the ileum.

The kidney does not seem to take on any special characteristics, presenting merely the appearances commonly termed cloudy swelling, and in the few cases in which I have made examinations, the capillary loops of the glomeruli being to a considerable extent bared of epithelium.

The cavities, seemingly abscesses, in the mesenteric glands show how great was the destruction in these tissues.

Microscopical study of the condition of the spinal cord in typhoid fever does not seem heretofore to have been pursued to a great extent. Of late years, too, improvements in microscopical technique render possible a much more accurate and satisfactory examination of delicate tissues like the cord than was previously possible. That there was considerable disorganization of the tissue in the case described is beyond doubt, and it presented itself in its highest degree in the postero-median columns in the cervical portion of the cord.

It is interesting to contemplate and to reflect upon one phenomenon presented in the disease, namely, the tendency of the blood to escape from the vessels in so many parts of the body. Hæmorrhage into a tissue, though not necessarily destructive, is always to a greater or less degree injurious, and in typhoid fever it is common from the nose and from the ulcers in the intestines, into the lungs, and sometimes into the substance of the heart. The condition, too, of the spleen and mesenteric glands would seem to present something analogous to hæmorrhage, for they are much enlarged and engorged with blood, but the nature of lymph-gland tissue is such that with present methods of microscopical examination it is not possible to be absolutely certain whether there is any escape of blood from the vessels or whether it is still retained within their walls. The abundant presence of red blood-corpuscles in such tissues is of course perfectly patent to anyone who has ever examined them with the microscope.

The amount of red blood-corpuscles that commonly lie in the pulmonary alveoli after death from typhoid fever, and the way that they alternate with areas presenting the appearances of pneumonic inflammation and exudation, how the hæmorrhage occurred and what changes it may undergo, have seemed to me questions of the greatest interest. This question of hæmorrhage into the lung in typhoid fever, if not actually new, is, I think, capable of being presented in a somewhat new aspect. Every clinician knows how common a symptom in typhoid fever bloody expectoration is. The importance of the condition of the lungs and the frequency with which they are involved is the turning-point upon which will rest the question of death or recovery—a matter which can hardly be given too great prominence. It is from the consideration of these turning-points in acute diseases I think that most can be done for the science of therapeutics.

The common practice in typhoid fever is to direct our therapeutic measures toward what is called the antiseptic method, toward the old expectant plan, or almost alone toward feeding, and again another physician will place his chief reliance upon the supporting effect of stimulants. This may be well enough in most cases, but I am quite convinced that, often, careful observation of the lungs and watchfulness to foresee the advent of more serious lung involvement, and well-directed efforts made to bring about a cure through therapeutic measures applied to the lungs, will conduce very greatly toward reducing the mortality record from the disease. By constantly keeping in mind the fact that the lung condition is of the greatest importance, and by wisely changing our course of management and medication when we see that these organs are about to become involved, or that their condition is likely to become worse, even to the extent of neglecting or setting aside all other treatment and directing our attention to the lungs alone, cases may be saved which would otherwise be lost. This, at least, is my impression, after a good deal of experience with the disease.

My object to-night has been not to make a pretence that I had a finished treatise upon the morbid anatomy

of typhoid fever to lay before you, but rather to call your attenion to such points of interest as, in my experience in the therapeutic management and pathological study of the disease, have come directly to my knowledge. For the disease is one which is so common that all physicians, whether they practise medicine or study pathology alone, are constantly called upon to deal with and to consider in its various aspects.

For my own part, I look upon it as a general condition, to be classed rather with diseases like smallpox or scarlet fever, which seem from their earliest stages to take hold of a large part of the system, though they have an invariable local manifestation, than with pneumonia, which begins locally in the lungs, and then by secondary involvement may invade other parts of the system to almost any extent. I am entirely unable, however the poison may have originally found entrance to the system, to see the reason for considering it to be truly a disease of the intestines. In many cases that I have attended there have never been, from beginning to end, any abdominal symptoms, no diarrhœa, no abdominal pain, no gurgling, no tympany—I have notes of cases in which, even from the beginning of the attack to the end in death, there was no loss of appetite. On the other hand, we all have frequently seen cases in which life was threatened or death occurred as a consequence of involvement of some other part of the system—the abdominal symptoms being, if not absent, at least so latent as to allow us to be quite sure that the threatened danger did not come from that quarter.

To show that I am not alone in such views as I have enunciated I will quote from an essay which seems to me a most admirable and suggestive one. In the Lumleian Lectures on Enteric Fever, by John Harley (*Lancet*, April 13, 1889), after discussing various *pros* and *cons* concerning the etiology of the disease, Harley makes the following statement: "From the foregoing considerations, I think it unreasonable to assent to the germ-theory of disease, and I can only regard it as another of the many instances in medicine and out of it where cause and effect have not been discriminated. Setting aside, therefore, this theory, I shall endeavor to prove that the disease under consideration is merely the effect of derangement of function." There is much more that is of interest in the essay, especially that it becomes evident as he unfolds his views that he tends to believe that typhoid fever may arise *de novo*. The germ-theory is of course the outcome and ultimate conclusion of the belief that the disease is local in the intestine.

There is another matter which I think is seldom given due weight in determining our prognosis in typhoid fever—the degree of our bodily perfection at the time we are attacked by any acute disease must largely influence our chances of recovery, and the degree to which our bodies are imperfect must render us more liable to disease. Does it not often happen that those who die of acute diseases had already in them some imperfection which took away the power to resist the depressing action of the acute process? Each attack from which we suffer and during which inflammatory processes take hold of any part of our tissues must leave us with a permanent mark—an imperfection—of greater or less degree. This thought is a very suggestive one and one which might perhaps be pursued with advantage to much greater length. In all cases of typhoid fever, therefore, we should, when dealing with them from the clinical standpoint, carefully try to ascertain if there was any preëxisting bodily imperfection which would make the prognosis more serious, and at our post-mortem examinations should seek equally carefully for the presence of lesions which were already present in the body before the attack came on.

Finally, let me recapitulate some of the points that it has been my desire to dwell upon and to elucidate.

1. The disease is in my estimation a general one, involving a large part of the system, and in no way a local disease of the intestine. This belief is supported by the many and extensive organic lesions found in the body after death; and thus it would seem likely that Harley is right in his statement that the disease is due in the first place to derangements of function, and in rejecting the germ-theory of its origin.

2. The frequency of hæmorrhages in various parts of the body and their importance, I have dwelt upon and I wish to repeat my belief that hæmorrhage into the substance of the lung is most common. This latter, if not a new observation, is a fact certainly not commonly known.

3. The observation that the spleen, mesenteric glands, and lymphoid tissue of the ileum are made up to a great extent of large multinucleated cells instead of the ordinary small lymphoid elements is a curious and interesting one and requires further study; such study may possibly lead in the future to something which may have practical value.

4. Careful microscopical study of the condition of the spinal cord in the disease is much to be desired.

5. The attempt is made to show the need of a careful consideration of the previous condition of bodily perfection of persons attacked by the disease as having an important bearing upon prognosis.

6. We should be influenced in our treatment of typhoid fever to a great degree by the manner in which it takes violent hold of this or that portion of the organism. Our therapeutic efforts will be much more likely to be crowned with success by a careful consideration of this matter.

In conclusion, I repeat that my wish has been to make my essay suggestive rather than final, to point to threads which if followed to their endings may lead to an advancement of our knowledge of the pathological anatomy of typhoid fever, for such an advance will surely lead us in the future to a better treatment, if not to that which would be best of all, the prevention of the disease.

ORIGINAL ARTICLES.

THE TREATMENT OF ORGANIC STRICTURE OF THE MALE URETHRA.[1]

By SEATON NORMAN, M.D.,
OF EVANSVILLE, INDIANA,
LATE ASSISTANT SURGEON U. S. MARINE-HOSPITAL SERVICE.

I HAVE endeavored in this paper to portray the subject of the treatment of stricture in a light

[1] Read before the Mississippi Valley Medical Association, October 10, 1890.

interesting to the general practitioner as well as to the specialist in genito-urinary diseases. I have not treated my theme as exhaustively as I should have done had I prepared the article for an association of genito-urinary surgeons, and I have contented myself with the discussion of the most recent and most approved methods of treatment in organic stricture of the male urethra.

Dilatation, interrupted or gradual.—In view of the elastic and distensible character of the urethra, it has been the time-honored custom to begin the treatment of stricture by the passage of suitable instruments. The urethra is injected with carbolized olive oil, and the largest bougie that can be passed through the meatus is slowly and gently guided as far as the neck of the bladder. If the meatus is not sufficiently large to admit an instrument corresponding to the normal calibre of the urethra, a preliminary meatotomy immediately suggests itself. This process of dilatation is repeated daily, or every second or third day, as the indications demand, until the canal resumes its normal dimensions, or the more urgent symptoms of contraction disappear. It is unnecessary to state that when the stricture or strictures are located in the penile urethra only, the curved sound is not the proper instrument to employ. Either the ordinary straight steel sound or Weisse's *bougie à boule* will produce the necessary dilatation in this portion of the canal, and the introduction of an instrument into the bladder is not only in most instances unnecessary but absolutely injurious.

In the practice of urethral surgery the operator cannot be too strongly impressed with the fact of the exquisite tenderness and sensitiveness of the urethra, and the slightest amount of force in the introduction of an instrument should be regarded as a relic of barbaric surgery. When commencing the treatment by gradual dilatation, in sensitive patients, I always produce local anæsthesia by injecting from twenty to thirty minims of a four-per cent. solution of hydrochlorate of cocaine. In the case of a stricture admitting a medium-sized sound, instead of injecting the carbolized oil it will be only necessary to lubricate the instrument, but in all instances in which we are dealing with a narrow or tortuous contraction, the passage of the sound will be greatly facilitated by the preliminary injection of oil.

Another point, which I think is not always fully appreciated, is, that we should never attempt to pass an instrument which will over-distend the stricture. I have seen the urethra rendered extremely sensitive and the process of dilatation delayed, sometimes for several days, by neglecting this simple precaution. As Brodie says, "The temper of the urethra varies as much as the temper of the mind," and the ultimate success of any method of dilatation must largely depend upon a thorough appreciation of this fact.

Instead of the steel sound it is the custom of Reginald Harrison, one of the best writers on the surgical diseases of the genito-urinary organs, to employ the flexible *bougie à boule*, and in inexperienced hands I think that this is the best instrument, inasmuch as with it there is little danger of injuring the urethra, and scarcely the possibility of producing a false passage. The cases of stricture amenable to this method of gradual or interrupted dilatation are those of recent date, those in which the urethra will tolerate the occasional instrumental interference, and those in which the patency of the canal remains intact after the employment of suitable dilators.

Continuous dilatation.—Continuous dilatation deserves but a passing comment. Since the introduction of Bank's whalebone filiform bougies the necessity for continuous dilatation has become more and more infrequent. By using successive sizes of this valuable instrument the narrowest stricture can at one *séance* be so thoroughly dilated as to admit a small-sized bougie, or the ordinary urethrotome. Of course, tight and narrow strictures, through which it is impossible to pass even a filiform bougie, will occasionally be encountered, but these instances must be exceedingly rare. Surely no genito-urinary specialist can afford to exclude from his armamentarium instruments so important and useful as Bank's filiform bougies, as they will render him good service in every case of annoying and troublesome stricture.

Internal urethrotomy.—Since the fear of rigors and urine fever has almost entirely vanished from the mind of the genito-urinary surgeon the internal section of the constricting tissues has deservedly become the most popular operative procedure for the relief and cure of organic stricture. The antiseptic precautions, and the subsequent attention to urethral asepsis, first practised, I believe, by Reginald Harrison, have rendered internal urethrotomy one of the safest of operations. In no case in which the specific directions of Mr. Harrison were strictly adhered to have I noted a single chill, and the fever, when any occurred, was only such as might supervene upon the performance of any minor surgical operation. It has been experimentally demonstrated by Bouchard, and practically proven by Harrison, that the cause of urine fever is the absorption of the toxic elements of the urine by the freshly-made incision. If, then, by any means, we can succeed in maintaining the wound aseptic, the patient will suffer from neither rigors nor fever; the cut surface will heal with a cicatrix that is less contractile than the previous cicatrix, and the

probabilities of permanent recovery will be greatly increased.

In discussing what I deem the most important and almost universally applicable operation for the radical cure of stricture, I will be pardoned for entering into the special details of the operation. The urethrotome that I now employ is Wyeth's modification of Otis's instrument, the only advantage of the Wyeth instrument being the cog-wheel attachment, which permits the incision to be made with greater accuracy. Dr. Gerster has recently brought before the profession a urethrotome for which he claims superiority because of the facility with which it can be separated into its component parts, and thus kept perfectly aseptic, but the Otis urethrotome can, I think, be rendered just as aseptic by boiling.

The urine in every case of stricture should be critically examined, and if the patient be suffering from suppurative disease of the kidney no operation should be advised.

As a rule, it is best to administer a general anæsthetic, unless it is against the especial request of the patient. It is a common custom with some surgeons to cocainize the part, and then to operate; but one cannot have the same freedom of manipulation, and the patient's struggles will often interfere with the thorough application of the method.

For irrigating the urethra previous to the operation I use warm Thiersch's solution. Having injected a small syringeful of four-per-cent. carbolized olive oil, I introduce the closed urethrotome beyond the deepest stricture. The instrument is then expanded until the resistance to the rotation of the screw is perceptible, and the knife is made to traverse the stricture from behind forward, and is slowly returned to its original position. The instrument is now still further expanded, and if any resistance still persists the cutting is repeated. I continue the dilatation to a calibre of 40, French scale, but rarely protrude the knife beyond the register of 30 or 32. A curved steel sound is next passed through the incision, the size of the sound corresponding to the normal calibre of the urethra operated upon. The sound usually employed for this purpose varies between 30 and 36 of the French scale.

After satisfying myself that all constricting bands have been divided, I introduce into the bladder a silk catheter or Tiemann's velvet-eyed soft-rubber catheter, draw off all the urine, and irrigate the bladder with warm Thiersch's solution. I then slowly withdraw the catheter until the solution escapes by its side from the meatus, so that the recent incision shall be rendered completely aseptic. The catheter is finally reintroduced just within the neck of the bladder, and secured in this position. The urine is thus gradually drained from the bladder, and is received into a covered receptacle in the bed, or conducted by a rubber tube to a vessel beneath. The catheter is usually permitted to remain in place for forty-eight hours, the bladder and wound being irrigated twice daily. After the catheter is removed the patient is directed to inject one or two syringefuls of Thiersch's solution after each micturition.

When these precautions and directions were strictly adhered to I have never known a rigor or an elevation of temperature to ensue. I have observed a rise of a degree or a degree and a half above the normal temperature during the first twelve hours after the operation, but this I consider has no relation to urine fever.

If, as is claimed by Dreyfous, Sahli, and others, the urine can be rendered aseptic by the internal exhibition of salol—the salicylate of phenol—there will be no necessity for the retention of the catheter. But in all cases in which the stricture is complicated by cystitis it is well to have the catheter retained, so that the bladder may be kept entirely free from urine. In three cases in which I operated in this manner I can record most satisfactory results. Salol, I think, is worthy of a trial.

Internal urethrotomy performed in this manner is, I believe, a perfectly safe operation. As a routine practice I give immediately after the operation five or ten grains of the sulphate of quinine, and a hypodermic injection of a fourth or a third of a grain of sulphate of morphine. The opiate allays the pain and nervous irritability, but it is a question whether the quinine is really of benefit, unless, perhaps, the patient has recently suffered from malaria.

In most cases, in the evening of the third or fourth day, the patient should be directed to micturate, after which a medium-sized sound is passed through the incision, and followed by an instrument large enough to distend the urethra gently. The patient should retain his urine as long as possible, and should be instructed to inject one or two syringefuls of an antiseptic solution immediately after micturition. When the incision is thus kept aseptic and clean the wound heals kindly, and there is much less danger of subsequent contraction.

When there is more than one stricture, as is usually the case, the deepest is divided first and the others in succession from behind forward.

In regard to the location of the incision, whether upon the floor or the roof of the urethra, I am in the habit of cutting, when necessary, in both positions. In strictures of long standing, and in those in which the constricting band can be distinctly felt, I think it best to make the division first on the roof, and then, reversing the urethrotome, repeat the procedure on the floor of the urethra. The absorption and final disappearance of the organized tissues of the stricture

are thus more likely to occur than when only the incision on the roof is employed.

The subsequent passage of sounds through the divided stricture is essential to the success of internal urethrotomy. As a rule, the sound should be passed every third day for a period of two or three weeks, and afterward once a week for two or three months. To obviate still further the probability of a recurrence of the contraction, it is best to pass the sound once every three months for one year.

I believe that if internal urethrotomy is properly and thoroughly executed, and if special care is exercised to maintain the patency of the canal until the wound is entirely healed, recontraction is of rare occurrence.

Authorities are divided in regard to performing internal urethrotomy in the bulbous or in the membranous urethra. Judging from the results obtained by Harrison, the combination of external and internal urethrotomy offers encouragement for the permanent cure of stricture. I have had only three opportunities to perform external urethrotomy without a guide, but the results as regards the non-recurrence of contraction were entirely satisfactory.

External urethrotomy with a guide is a simple operation, can be performed with facility and rapidity, and promises more satisfactory ultimate results than internal urethrotomy performed in the deep urethra.

To enter into the details of the combined operations, as well as to discuss the various operations for the so-called impermeable strictures, would increase the size of my paper far beyond its proper limits.

In conclusion, I wish to say that of the various scales that have been proposed for urethral instruments, only the French system is worthy of consideration. To have a urethrotome graduated in millimetres—and all of them with which I am acquainted are so graduated—and sounds corresponding to the English scale, is a manifest absurdity.

ACUTE DYSENTERY AND THE AMŒBA COLI.[1]

By ALFRED STENGEL, M.D.,
RESIDENT PHYSICIAN TO THE PHILADELPHIA HOSPITAL.

The following cases of acute dysentery illustrate some points in the symtomatology and treatment of this disease, and furnished the material for some investigations into its etiology:

Case I.—Mary D., seventy-three years old, has been an inmate of the hospital for many years, during which she has had various illnesses. She is known to have had albuminuria, with granular casts. On September 19, 1890, patient was seized with dysenteric diarrhœa, severe and typical from the first. The stools were rather large and very frequent, and contained mucus and blood, but were unaccompanied by severe distress. There was fever, with great depression. The patient was given arsenite of copper, at the outset in doses of $\frac{1}{100}$ of a grain three times during the night, and in smaller doses every twenty minutes during the day. Ice suppositories, about the size of the thumb, were also used every three hours, but no relief was obtained. The stools became larger and more hæmorrhagic, the general depression increased, and the condition seemed more and more that of uræmia. Later, bismuth and astringents were tried, but without avail, and the patient died on September 22d, three days after the onset of the disease.

Autopsy showed a distinct ulcerative colitis and proctitis. No membrane was present, but small ulcers and much extravasated blood were found in the mucous membrane.

Case II.—Patrick T., aged forty years, a laborer, admitted August 25, 1890. Patient was stout and healthy in appearance, but has used alcohol to excess, and has lived a life of hardship. He said that he had had diarrhœa for several weeks, and that he had been drinking heavily at the same time. When admitted he complained of great pain in the lower part of the abdomen, some pain in the legs and arms, great thirst and gastric irritability. The stools were very frequent, attended with much tenesmus, and consisted of stringy mucus, streaked with blood. The temperature was slightly elevated; the pulse was rapid and weak. He was given bismuth subnitrate with paregoric and syrup of ipecacuanha every two hours. No relief was obtained from this treatment, which was continued two days. Later, acetate of lead and opium were given, with an occasional opium suppository. The latter proving irritating, and being discharged immediately after insertion, suppositories of ice were used instead, with great relief.

Under this treatment the tenesmus entirely disappeared, the stools became larger and free from blood and mucus, and the man's general condition improved. The temperature, however, made long daily excursions, reaching 102° or at night higher, and falling below the normal in the morning. As the diarrhœa still continued to be excessive and accompanied by considerable abdominal pain and tenderness, an astringent diarrhœa mixture was given, with no better result. The pains or cramps were sometimes unusually severe; at such times the pulse became extremely rapid and small, the features pinched and blue, and the extremities first cold, then bathed in a profuse perspiration. Salicylate of bismuth in doses of 10 grains every two hours was next used, and under this treatment the patient slightly improved. There still remained excessive diarrhœa, with great weakness, and occasional pains which were sometimes severe, more often slight, and in spite of salicylate of bismuth, and, later, thymol, the case still remains in about the same condition. The temperature has made longer excursions, falling lower and rising higher than at first. The tongue is dry and coated, the pulse is

[1] The cases reported in this paper occurred in the service of Dr. F. P. Henry at the Philadelphia Hospital.

weak and rapid, and the man is very weak, though not markedly emaciated.

CASE III.—Joseph Q., aged thirty years, a cigar-maker, was admitted to the wards on September 30, 1890, while intoxicated. Patient is an alcoholic, and has had malarial fever several times. He gave a history of having had diarrhœa for four or five days. The stools were very frequent, and accompanied by much tenesmus, soon becoming small. They contained mucus and blood, and were discharged involuntarily. On admission his temperature was $101\frac{3}{5}^{\circ}$, pulse 110, and respirations 18. The face was flushed, and there was considerable pain in all parts of the body. No disease of the lungs. The heart was acting very rapidly, and with a distinct galloping rhythm, especially marked at the apex. The urine was high-colored, and contained a trace of albumin, but no casts. The evacuations were very frequent and painful, and, as stated above, typically dysenteric.

Treatment with ipecacuanha and morphine was first adopted. Of the former, an initial dose of 30 grains, followed by 10 grains every two hours; of the latter, small doses preceding the ipecacuanha were given. This treatment was continued for one day without inducing vomiting, excepting after the first dose, but without influencing the course of the disease. Ice suppositories were employed at the same time, but no good effects were derived from them. At the end of the day, treatment was changed to magnesium sulphate 40 grains, deodorized tincture of opium 5 minims, with syrup of lemon and water, every hour until four doses had been given, when the stools became large, dark, and free from mucus and blood. The mixture was then given every two hours during one day, when the changed character of the stool was fully established, and the pains were entirely relieved. Bismuth subnitrate and powdered opium were then used. A slight reappearance of the mucus required a temporary return to the magnesium sulphate mixture, but convalescence was fully established on the fifth day.

The fever in this case was moderate, but continuous, and the general condition was not much impaired, although there was some abdominal tenderness, especially on the left side.

CASE IV.—Emily F., aged seventy-two years, has been in the hospital for several months, suffering from chronic nodular rheumatism. She slept in a bed near that of Case I., and after the death of the latter her bed occupied the place made vacant. On September 28th, the patient began to suffer with diarrhœa, which soon became dysenteric. The stools were frequent, small, mucous, and bloody. There were much straining, abdominal pain, general depression, loss of appetite, and excessive thirst, but no elevation of temperature.

Salol in doses of 10 grains, combined with opium and ipecacuanha, was first tried, but gave no relief. Then the magnesium sulphate mixture was used, and after three or four doses the stools became large, brown, and painless, then less liquid, and less frequent, when bismuth and opium were substituted for the magnesium sulphate. For the great tenesmus which was a prominent feature in this case, ice suppositories were used with surprisingly good result. A temporary return of mucus in the stools required a return to the magnesium sulphate, but permanent relief was soon obtained, and the case convalesced. There was some abdominal tenderness in the left iliac region during the progress of the case.

CASE V.—Robert D., aged forty-eight years, is a stretcher-carrier in the receiving ward of the hospital, and is frequently called up at night. On the night of September 30, 1890, he was up several times, and became overheated. He had several loose, semi-liquid stools before morning, and on the next day began to have very frequent discharges, all of which were mucous and bloody, and were attended with much straining, and general as well as abdominal pain. There were slight fever, excessive sweating, loss of appetite, and great thirst.

On the morning of October 2d, the patient began to take arsenite of copper in doses of $\frac{1}{100}$ of a grain every two hours, but did not improve. Then the magnesium sulphate was used, and after a few doses the stools became painless and free, the general depression less marked, and mucus and blood disappeared from the discharges. The mixture was continued for a day longer, when bismuth and opium were substituted, and the case progressed favorably. In this case also there was a temporary reappearance of mucus in the stools, and some pain, but a few doses of the magnesium sulphate sufficed to relieve this. There was slight but continuous pain in the abdomen, especially in the left iliac region.

A summary of the important features presented by these cases may not be out of place.

The tendency of dysentery, especially in its less grave varieties, to begin with ordinary diarrhœa, is well illustrated in four of our cases, while the fifth case confirms the old observation that when overwhelmingly severe the disease is likely to be dysenteric from the start.

The character of the pain was similar to that which has often been observed, but the abdominal tenderness so prominent in four of our cases is not referred to in the text-books. This tenderness was slight in three of the cases, and excessive in one, was nearly constant, and was most marked in the left iliac region.

As to the propagation of the disease, it is interesting to note that in one patient in the same ward and adjacent to Case I., and in two other similar instances, mucous and slightly blood-tinged stools were observed (Cases III. and IV.).

Conclusions as to the effect of various plans of treatment can hardly be drawn from so few cases, but the observations may be of value in connection with those of others using similar methods.

In two cases ipecacuanha was employed—small doses in one, large in the other—but no change in the character of the stools or the course of the disease was observed.

Arsenite of copper, lately so much lauded in the

treatment of dysentery and diarrhœa, was used in three of the cases, first in minute then in larger doses, but no good whatever resulted, though at least one of the cases was favorable.

Salol was used in one case in doses of 10 grains, but was without effect. The mixture of magnesium sulphate with deodorized tincture of opium, syrup of lemon, and water, was given in three cases, after other measures had failed, and in each, after a very few doses, the character of the stools changed, the pain lessened, and no doubt the course of the disease was cut short. There was a tendency to relapse in each case, but a few doses of this mixture checked it, and convalescence was otherwise uninterrupted. Whatever the results that have been obtained by other remedies, certain it is that in these cases the magnesium sulphate served to alleviate suffering most promptly, and to check the progress of the disease.

In three of these cases suppositories of ice were used, in one after opium suppositories and enemata had been rejected. In two the results were most gratifying, the pain disappearing almost instantly. In the third, however, no effect was observed. It is difficult to say whether the number of stools was lessened by the ice, but when used at once on the occurrence of pain the interval between the stools seemed to be materially increased.

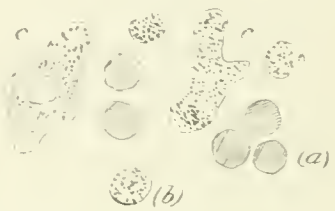
Renewed attention in this country has been called to the examination of dysenteric stools by a recent paper by Osler,[1] confirming the observations of Losch, Lambl, and Kartulis, who have found the amœba coli in the discharges of cases of ulcerative colitis, chronic diarrhœa, and dysentery, as well as in the abscesses succeeding such cases. Osler reports a case of chronic dysentery with abscess of the liver, in which examination of the stools and pus of the abscess revealed large numbers of the amœbæ. Our investigations have been confined to three cases (Cases III., IV., and V.), and in each the amœba was found in more or less abundance.

Macroscopically, the discharges of Cases III. and IV. were much alike—small, rather stringy, mucous, and blood-tinged. The appearance of the stools of Case V. was slightly different, being more lumpy, containing larger masses of blood, and more suggestive of a diphtheritic condition of the bowel.

Microscopically, there was but little difference. The stools of Case III. were examined on October 1st, the day after the patient's admission to the hospital. Large numbers of red corpuscles and pus corpuscles were found, besides many bacteria of different kinds, micrococci and bacilli, in active motion, predominating. Easily distinguishable from the other elements and very numerous, were the large amœbaform bodies first described by Losch. They were conspicuous by their size, which ranged from 10 to 30 micromillimetres; by a more brilliant appearance of the protoplasm than was seen in the other bodies, by the constant active amœboid motions: and by the presence within them of both large and small vacuoles, or hyaline bodies. All portions of the mucous stools contained them, but they seemed most numerous in the small blood-stained masses. The protoplasm was granular and distinctly outlined, and contained large numbers of pigment granules in active motion. When at rest the bodies were round or ovoid, but long, finger-like prolongations were frequently extended, and the pigment granules were mainly aggregated at the extremities of these. Some of the amœbæ had distinct nuclei, and a few hyaline bodies or vacuoles.

Figure 1 represents the appearance seen on the first day.

FIG. 1.



a red corpuscles. *b*. leucocytes. *c*. amœba coli.

Subsequent examinations were made daily, or whenever mucus appeared in the discharges, with substantially the same results. On October 2d the number of amœbæ had already decreased, and the movements were much less active. Vacuoles now were more commonly observed, and were sometimes quite large, and a few were partially surrounded by pigment granules, as described by Osler. The number of vacuoles in each amœba varied from one to several. The movement of the protoplasm was slower and less evident, as was also that of the pigment matter.

FIG. 2.

Figure 2 represents the appearances seen in the discharges of Case III., on October 3d, two days after the onset of the disease, and confirmed those previously made.

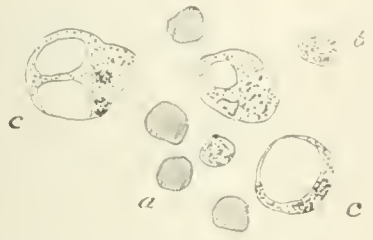
The organisms in Case IV. were smaller, the vacuoles more prominent, and the movement of the

[1] Johns Hopkins Hospital Bulletin, May, 1890.

pigment grains less active. The stool was somewhat old, and was cold when examined. Subsequent examination showed less, but still quite numerous, amœbæ.

Figure 3 represents the appearances of the stools in Case IV. In this case the first examination, made four or five days after the onset of the disease, showed but few of the organisms, which, however, presented the same picture as those seen in Cases III. and V.

Fig. 3.



The attempt to stain the amœbæ with methyl-blue and fuchsine failed, but Kartulis says they can be beautifully colored with eosin.

On October 7th mucus taken from one of the large brown stools of Case IV. was injected into the rectum of a guinea-pig, but after eight days no result has been obtained.

AN INQUIRY INTO THE CAUSE OF ALARMING AND FATAL RESULTS FOLLOWING ATTEMPTS AT THE RADICAL CURE OF HYDROCELE.[1]

By OSCAR H. ALLIS, M.D.,
SURGEON TO THE PRESBYTERIAN HOSPITAL, PHILADELPHIA.

I wish to state at the outset that this paper is confined to the subject-matter embraced in the title, and that it has nothing to do with the anatomy, etiology, pathology, or diagnosis of hydrocele. Its purpose is to take up the three widely-accepted methods of dealing with hydrocele, viz., treatment by injections, by the seton, and by the open method; to give examples of casualties of a most serious nature that have attended each; and to present the reasons that have suggested themselves to the author for the too frequent occurrence of such accidents.

And first, let me state why I selected the subject. In the spring of 1882 an aged colored man was sent to the Presbyterian Hospital, suffering from retention of urine. His penis was withdrawn into the scrotal tissues, as is not infrequently seen when large hydroceles are present, but not, as sometimes happens, offering an obstacle to catheterization.

I was about to tap and inject the sac when my colleague, Dr. Porter, said to me, "I would be careful what I did to that man, as I lost a similar case not long ago." Scarcely realizing his statement, yet in deference to his suggestion, I simply tapped the hydrocele, and waiting for reaccumulation, tapped a second time in a fortnight, and injected alcohol. A few weeks later the patient left the hospital with a scrotal tumor, as we all supposed, undergoing the changes so commonly seen in the course of radical cure. A few weeks later I was sent for to see the man at his home. The scrotal pouch was crepitant, gas was escaping at one or more small openings, the general constitutional symptoms of septicæmia were present, and though I promptly laid open and depleted the tumor at many points, the old man gradually sank and died. Here were two deaths, and as I had been invited to prepare a paper for the Philadelphia Academy of Surgery, by its president, the elder Gross, I selected this subject.

I sent letters to one hundred and fifty physicians requesting them to give me a report of the disasters that had occurred in their practice from the radical treatment of hydrocele. About fifty replied, and from their answers I am enabled to present the following interesting data:

Abscesses—*from the employment of the seton.*

Dr. H. M. "I have had abscesses follow the use of the seton."

Dr. L. I. "In my practice two out of three had abscesses when I used the seton."

Dr. A. N. "With the seton only two abscesses occurred in twenty-eight cases. Of these one was in the scrotal tissues, the other occurred in the pelvis and broke into the bladder; ultimate recovery."

Dr. T. I. "I usually employ a drainage-tube. In one case it was withdrawn by the patient. I restored it and an abscess followed."

Dr. M. A. "I have had abscesses follow the use of the seton."

Dr. C. O. "In a double hydrocele, after failure with tincture of iodine, I employed the seton. Cure on one side with abscess, on the other without. In a case in which tincture of iodine had failed a cure was effected with the seton—and abscess."

Dr. M. C. "In three consecutive cases in which I employed silver wire I had abscesses."

Abscesses—*from injections of iodine.*

Dr. G. R. "I abandoned the tincture of iodine years ago on account of pain and abscesses."

Dr. B. T. D. "I have had repeated abscesses from the use of tincture of iodine—from one to two drachms."

Dr. W. E. "Twenty-five per cent. of my cases treated with the tincture of iodine have had abscesses."

[1] Read before the Philadelphia Academy of Surgery, October 2, 1890.

Dr. D. N. "After injecting the tunica vaginalis testis I purposely scratched the lining of the sac with the canula. In this case a fearful abscess occurred in the scrotal tissues."

Dr. D. R. "I have had suppuration follow the use of tincture of iodine with no remedial effect."

Dr. L. E. "Abscesses and suppuration are no guaranty of a cure. Fifty per cent. of injections with tincture of iodine fail."

Dr. W. P. H. "I injected a healthy adult with tincture of iodine. Intense pain followed, with great local swelling and inflammation. Prompt measures were taken to control the inflammation, but an abscess resulted."

Dr. C. O. L. "I have found injections so unsatisfactory, so likely to give rise to abscess and sloughing, that I never resort to them any more."

Shock and Severe Pain.

Dr. T. L. "Out of ten cases treated with tincture of iodine three injections were immediately followed by excruciating pain; and of the three, one was cured with abscess, and in two, though the injection produced agonizing pain, the result was a failure."

Dr. O. T. "Shock and extreme pain in the testicle followed an injection of the tincture of iodine. The shock and faintness lasted for more than an hour."

Dr. C. R. "I came near having a death in my office from injecting two drachms of deliquesced carbolic acid. Great shock and pain: the patient became cyanotic and pulseless, and but for galvanism I think the man would have died. Still the hydrocele was not cured, and I was obliged to resort to the tincture of iodine to effect a cure."

Hæmatocele.

Dr. M. E. "I have had a hæmatocele follow the injection of dilute tincture of iodine, one-third strength."

Dr. H. A. "I was called to see a person suffering from a large hæmatocele. He had a few days previously been tapped and injected with tincture of iodine."

Dr. R. E. E. "I have had one hæmatocele follow tapping and injection with iodine."

Orchitis.

Dr. T. L. L. "Two cases of violent orchitis followed the injection of tincture of iodine, U. S. P."

Dr. A. S. H. "Orchitis with persistent hypertrophy of the testicle followed the use of the trocar and subsequent injection with tincture of iodine."

Dr. S. B. R. "I think epididymitis is a very frequent result of injections of tincture of iodine into the sac of the tunica vaginalis."

Sloughing of Scrotum.

Dr. G. A. R. "I have had the entire scrotum slough after injections of the tincture of iodine. In a second case the entire scrotum sloughed, and the sloughing process extended into the inguinal region—from the use of the officinal tincture of iodine. I have also had sloughing at the entrance and exit of a seton."

Dr. M. I. N. "I have had sloughing of the scrotum occur in my efforts to cure hydrocele."

Dr. K. I. N. "In a case of very large hydrocele that extended nearly to the patient's knee, there were sloughing and gangrene as the result of attempt at radical cure."[1]

Dr. W. A. R. "I have known sloughing of the scrotum to follow frequently the introduction of the seton."

Dr. P. I. L. "Gangrene of the scrotum and death occurred in a young child into whose tunica vaginalis I had inserted a single silk thread, and which I withdrew in twenty hours."

Dr. C. O. L. "I have witnessed sloughing of portions of the scrotum from injections."

Dr. M. A. R. "I have often seen sloughing of the scrotum after using the seton."

Dr. M. E. A. "Slight sloughing of the scrotum followed the injection of two ounces of port wine. It was left in the sac about twenty minutes."

Dr. C. R. "I had a case of hydrocele from which I withdrew three pints. Repeated simple tappings three or four times. Then I injected tincture of iodine, U. S. P. Sloughing of scrotum, exposure of both testicles, and narrow escape from death."

Dr. B. G. S. "When I was a medical student I witnessed the sloughing of the entire scrotum and narrow escape from death as the result of injection of tincture of iodine."

Dr. B. T. R. "Sloughing of the scrotum and pyæmia has occurred twice in my practice—once after injecting tincture of iodine, and once after the use of a seton."

Dr. A. L. L. "Sloughing followed the injection of iodine in a case in which a hæmatocele occurred, and to relieve which incision was employed."

Dr. S. T. O. "I have had sloughing follow excision of a portion of the tunica vaginalis testis."

Dr. R. O. S. "After injection with tincture of iodine the scrotum sloughed and the testicle perished. In this case the patient had hurt his scrotum the day before while riding a fractious colt."

Dr. L. E. A. "Sloughing and exposure of the testicle followed the injection of the tincture of iodine, two drachms. In this case the man went on a spree after the injection."

Dr. W. W. W. "My preceptor, a clinical teacher

[1] Treatment not given.

and eminent surgeon, came near losing a patient; after introducing a seton violent inflammation and extensive sloughing."

Dr. W. W. W. "My colleague in his practice had the upper part of the scrotum and cord slough away after the injection of a twenty-per-cent. solution of carbolic acid."

Alarming Symptoms—*developed in the course of treatment, with narrow escape from death.*

Dr. G. A. "I came near losing a case recently in the employment of my favorite method—the seton. The man certainly had a narrow escape from death."

Dr. W. I. R. "In a case under my care in which two flaxen threads were introduced, there were profound constitutional disturbance, high fever, profuse perspiration, and for a time matters looked very gloomy and threatening."

Dr. C. A. R. "In one case, where both testicles were exposed after using a silver-wire seton, the patient pulled through by the skin of his teeth. He had a most serious septic involvement, with numerous abscesses and prolonged tedious recovery."

Dr. B. G. S. "In one case, after injecting tincture of iodine my patient came near perishing, and escaped after sloughing of the scrotum."

Dr. J. W. H. "I saw a child five years old treated with the seton. Violent symptoms. The patient was alarmingly ill for several days. Belly became tympanitic and all the symptoms of localized peritonitis were present. In this case a single silk thread was introduced and permitted to remain twenty-eight hours. The operator was a practical hospital surgeon."

Dr. J. W. H. "I injected a robust fireman with deliquesced carbolic acid. Violent inflammation followed with vomiting, tympanites, high temperature and rigors. An abscess formed, free incisions were made, and the patient slowly recovered."

Deaths.

Dr. T. I. F. "I have known a death to follow simple aspiration of a hydrocele, *i. e.*, emptying it with an aspirating needle without subsequent injection."

Dr. P. R. C. "Death followed incision of the scrotal pouch to relieve hydrocele, ten days after the operation."

Dr. L. S. P. "A death occurred in my practice in a case in which I employed a single silk thread. The child died from septicæmia and gangrene. The thread was only left in twenty hours."—Reported in the *Annals of Surgery*.

Dr. B. Y. R. "I have known death to follow the use of the exploring needle without injection."

Dr. O. H. A.[1] "Death from septicæmia followed the injection of alcohol."

Dr. W. G. P. "Death followed in about ten days after the injection of tincture of iodine in an old negro under my care."

Dr. A. N. D. "My preceptor lost a case from injecting the tincture of iodine. He was a famous clinical teacher and had had large experience in the treatment of hydrocele."

Dr. B. F. N. "I saw a case in a dissecting-room that I recognized as having been injected a short time before in a college clinic. The scrotum was greatly distended."[2]

Dr. R. O. C. "I have known death to follow ten days after the simple evacuation of a hydrocele with a small trocar."

Dr S. E. X. "I have never had a death in my own practice from the treatment of hydrocele, but I witnessed one that occurred in the practice of a neighboring physician."

Dr. A. T. L. "When a medical student I witnessed death following the treatment of hydrocele."

Dr. W. R. R. "Two deaths have occurred in my practice from incision for the radical cure of hydrocele with thickened sac. One operation resulted in pyæmia, the other in gangrene of the scrotal tissues."

The following is a condensed tabular report of the cases:

Casualties.	Number of surgeons reporting.	Number of cases operated on.
Death[3]	12	13
Sloughing of scrotum	14	17
Abscesses[4]	14	...
Narrow escape from death	4	4
Pyæmia, with ultimate recovery	5	6
Hæmatocele	4	4

A glance at the list of casualties shows that abscesses are very frequent. Some of my correspondents attribute the occurrence of abscesses to their own carelessness. They think that the canula probably slipped, and that a part of the injection was thrown into the connective tissue of the scrotum. Such a mishap is possible, but not in any degree probable.

When a hydrocele is tapped two conditions should be borne in mind: one, *that the sac is tense and tough*—it is often distended almost to bursting. The second condition is that the trocar so universally

[1] Alluded to in the opening of the paper.

[2] This case is of doubtful value. My informant did not examine the scrotal tumor nor make an autopsy.

[3] Deaths 1, mode of treatment not stated;
3 from aspiration without injection.
4, injections with tincture of iodine.
1, injections with alcohol.
1, from the use of the seton.
3, following incision into the sac.

[4] For list of abscesses see body of paper.

used for withdrawing the fluid is a *blunt instrument;* hence, when it is thrust through such a dense, tough, tense membrane a hole is formed which, when the canula is withdrawn, will permit of the passage of fluids either way. This view is sustained by clinical observation. It is an almost universal experience that a puncture of the sac, whether by a surgical needle or by an extremely fine operating or hypodermic needle, will be followed by leakage until the sac is emptied. Some of my contributors have employed no other method than tapping for many years. It is plain, therefore, that the puncture permits fluids to pass *from* the sac. Again, it is clinical experience that hæmatocele may follow the puncture of the sac. In my own opinion, blood in a varying degree *always* pours into the sac after the withdrawal of the canula. If capillary vessels only have been transfixed the hæmorrhage will not be great; but if vessels of considerable size have been cut, a hæmatoma may be formed—as has been reported—the size of a fœtal skull at full term.

It seems, therefore, readily demonstrable that after the use of the trocar fluids may flow from the sac-walls into the sac-cavity, and from the cavity into the connective tissue. Hence, when my correspondents confess that abscesses occur from injecting the cellular tissue, and are due to their own carelessness, I dismiss the confession, since it admits too much and accounts for too little.

The graver conditions, reported by fourteen of my correspondents, of sloughing of the scrotum occurring after injections and the use of the seton, are to be explained by excessive inflammation. The swelling that arises, sometimes the result of recklessness on the part of patients, and sometimes due to the injected fluid or seton, transcends the limit of nutrition. The nutrient supply, never great in the scrotal tissue, is choked, and the tissues starve. The general sloughing is only an exaggeration of the milder and more controllable abscess.

But a class of mishaps of the gravest character remain to be disposed of—those cases in which septicæmia occurs. Every death, I believe, was from this cause, and the question arises, What is the pathology? It has long beeen a clinical observation that old hydroceles with hypertrophied walls do not collapse as do young and recent hydroceles. In all chronic cases the fluid, at first, flows from the canula in a full stream, but stops flowing long before the sac is empty. Now, many clinical teachers claim that the reason the tincture of iodine fails, is that the operator is not careful to empty the sac entirely before injecting it; the operator, therefore, kneads the sac, and in a few moments the fluid begins to flow from the canula in a stream. A repetition of the kneading process brings, after a few minutes, a second flow of fluid, and thus, by a little delay and patience, the operator entirely empties the sac. But alas, the patient must pay dearly for the surgeon's perseverance! The emptying of that thickened sac was possible *on one condition only*, viz., the introduction of an amount of air equivalent to the amount of fluid to be displaced. With an open canula in the hydrocele, just so much fluid escaped as the compression of the atmosphere could force out. The fluid from a tapped hydrocele flows out, not because the tissues of the hydrocele are contractile; the flow is due to atmospheric pressure, and when atmospheric pressure has a hypertrophied sac to deal with, the fluid ceases to run the moment that equilibrium is established. To act further on the walls of the sac and to drive out more fluid are impossible; hence, air enters the canula, and with it the tendency to a vacuum is overcome, and the fluid flows.

The injection is now thrown into a sac emptied, it is true, of hydrocele fluid, but filled *with air*. What follows? The injection lights up inflammation; new products are thrown out; heat, moisture, air, and decomposing blood, in a closed sac, offer a field for germ-proliferation second to none in the domain of surgery; and septicæmia, the result of putrid absorption, occurs.

The interrupted flow of fluid from an old hypertrophied hydrocele may be imitated by a glass bottle, to which an elastic India-rubber bladder is attached, with perforated rubber tube, extending throughout the bladder and to the bottom of the bottle. This apparatus represents a hydrocele upon which the atmosphere can act to a certain degree, but which cannot be wholly compressed. If the bladder and bottle are now filled with water and inverted, the fluid will flow in a stream until the rubber bladder is emptied; but the bottle, which cannot contract, remains full. But in a few moments air will enter the tube and run bubbling through the water in the bottle, when water will again flow through the pendant tube. It will flow for but a moment, since only a little air found its way through the tube, and only a little fluid can escape to equalize it; but, after a few minutes, more air will rush bubbling through the bottle, and be immediately followed by a jet of water from the tube. Thus, little by little, the bottle will be *emptied* of water *and filled with air*.

But, it will be asked, how about the three deaths from excision? Had I never had any experience with the open method I would be at loss to explain them, but experience has taught me that the best principles will miscarry when executed in a faulty manner.

In one of my cases of incision septicæmia developed and bid fair to do serious mischief, but when I extended the incisions to give dependent drainage, improvement promptly resulted.

Few surgeons, I am convinced, do their first open operation perfectly. The opened and emptied sac shrinks somewhat, the length of the incision is shortened, the sac becomes a cup for the retention of secretions, and serious, if not fatal mischief results. No experienced surgeon is satisfied with an opening that will admit "two finger-ends," yet such operations are performed and denominated *incisions*. The open method demands that the whole interior of the sac shall come under scrutiny; that the excess of tissue in the sac shall be retrenched, unhealthy granulations, laminated fibrin, and all diseased tissue removed; and that ample dependent and unobstructed drainage is established.

A few practical considerations will conclude this article. Most of the casualties reported occurred at a period when modern surgical views were unknown. Some of the accidents may be traced, no doubt, to want of care in the performance of the operation. The trocar and canula may be said to be unsurgical instruments, because they are uncleanly instruments, and the smaller they are the more unlikely they are to be clean. So, too, with a seton; none but the modern surgeon would think of using sterilized silk, and there can be no doubt that uncleanly materials have often imparted a disease of greater magnitude than that which they were intended to cure.

If I may be permitted to express a preference for a mode of treatment I shall unqualifiedly endorse the open method. By no other method is anything like a diagnosis arrived at. True, before using the trocar care is taken that it be not thrust into a hernia or a sarcoma, but when the elimination is made and the surgeon is sure that fluid is present, if he be asked the cause of the fluid or the condition of the sac, the testicle, or the epididymis, he can reply with conjectures only.

By the open method the eye is enabled to see and the fingers to feel all parts of the sac, and if the operation is done with surgical skill and surgical completeness there will be no unpleasant sequelæ and no tardy recoveries.

The contributors[1] to this article were either men who had devoted their lives especially to surgery or men of large general surgical experience. Two inferences may be drawn from their contributions, namely:

That either their methods must have been very faulty and their results very unfortunate; or, that the surgical treatment of this affection in the hands of the profession generally has not been honestly reported.

If it be said that the methods were faulty in pre-antiseptic days, it must also be confessed that all employed the same methods. If it be said that the operators were unfortunate, I reply that among the most unfortunate are names that add lustre to American surgery.

I shall let the reader form his own conclusions upon the *second* inference. For myself I will simply say that clinical assistants can give a longer list of disasters than clinical professors. I will not say in regard to this operation that surgeons would make a misstatement, but I am convinced that they have wonderfully short memories.

1604 SPRUCE STREET.

[1] I have purposely withheld the names of my contributors. Some of them generously told me to make any use of their names and correspondence that I desired. But so long as the surgical faculties in our great colleges make no reports of their casualties I will not subject my contributors to the unjust aspersion that their sad results were attributable to lack of skill.

DISCUSSION.

In discussing this paper DR. WILLIAM HUNT said that his experience with the treatment of hydrocele has been so favorable that he had no adverse results to report. He recalled an abscess or two in hospital work, especially with the use of the seton, and while there were cases that have not recovered promptly after the use of iodine and carbolic acid, as well as after the open method of treatment, he recalled no untoward results. He asked Dr. Allis whether his record had any reference to the time before the introduction of antiseptic methods. Formerly, in the instrument-rooms of hospitals, there was no instrument so dirty as the trocar, because the essential parts were hidden from view; and the question arises, How much did that have to do with the accidents noted?

DR. WILLIAM G. PORTER said that he was much surprised to hear of the great mortality of operations for hydrocele. His own experience has been almost uniformly favorable, although he has had one case in which the injection of iodine was followed by death, in an old man. In that case the patient's age was apparently the only contraindication, and there were no symptoms of septic trouble, death apparently being due to exhaustion seventy-two hours after the operation.

The subject is one in which we are all interested, because all surgeons are constantly called upon to perform the operation. His preference is for iodine, and with the single exception mentioned he has seen no bad results from it, and can recall but one case in which it failed to cure.

Last spring he had an interesting case of hydrocele, in a child less than two years of age. Such cases he has almost always succeeded in curing by the external application of iodine and evaporating lotions, but in this case external applications had no effect. He then tried simple tapping, but this also failed, and after the fluid reaccumulated twice he used the seton, which was followed by cure. On account of the tender age of the patient, he was afraid to inject iodine.

He recently had a rather embarrassing experience, and one which he has not seen described. He was called to operate on an ordinary hydrocele, which he had examined by transmitted light, and which he was satisfied was a true hydrocele. He plunged a trocar into the centre of the sac without difficulty, but on withdrawing the

canula, to his great consternation no fluid followed. He knew that the trocar had penetrated the sac, and he moved the instrument in various directions, but could not get a drop of fluid. He then ran a long probe through the canula in all directions, but still failed to get any fluid. He then tried to aspirate fluid by means of a long-nozzled syringe, but without success. Examining the swelling again by transmitted light, it was found perfectly translucent. On moving the trocar again, a drop of mucus-like substance came out and the fluid began to escape. He has not used the open method, as the injection of tincture of iodine has been satisfactory.

Dr. John B. Deaver said that his experience with the tincture of iodine was limited, but that he has operated on a large number of hydroceles by the open method, and has seen bad symptoms follow but once. He opens the tumor from the top of the scrotum to the fundus, and dissects out the parietal layer of the tunica vaginalis. The one unfortunate sequel occurred because he was in a hurry, and was not careful to see that all hæmorrhage was arrested. A hæmatocele followed, which broke down and suppurated. The patient was etherized, the broken-down clot removed, and the parts rendered aseptic and drained. The patient made a good recovery. Success in this operation depends upon perfect cleanliness, complete arrest of hæmorrhage, and draining. He always uses a large rubber drainage-tube.

While recently operating for the radical cure of hernia, he attempted to remove the entire sac, and disturbed the parts so much that in forty-eight hours the man had an acute hydrocele. Ten days later he successfully operated on the hydrocele.

He thought that the results recorded by Dr. Allis could in most cases be attributed to the introduction of germs by dirty instruments. In the use of tincture of iodine, if there is but one sac, the operation should be successful; but if there are two or three sacs not in communication with each other, the operation will fail.

His experience in the treatment of hydrocele in children is not large, but he has succeeded in bringing about a cure by tapping and scarifying the tunica vaginalis with the end of the canula. He has not done the open operation in children, although, should the occasion arise, he would not hesitate to do it. He would first try tapping and scarifying, unless these had previously been done. In cases of recurrent hydrocele he would do the open operation. The pain after the use of tincture of iodine is considerable, and epididymitis, or even peritonitis, might follow, but such results are not to be expected after the open treatment.

Dr. J. Henry C. Simes said that in the treatment of hydrocele his experience has been chiefly with tincture of iodine. During the past two or three years, in order to prevent the very severe pain which so often follows the injection of the iodine, he has injected through the canula two drachms of a five-per-cent. solution of muriate of cocaine, which is allowed to remain in the sac for a few minutes, and then drained off. The iodine is then thrown in, and it is a very exceptional occurrence for the patient to complain of pain. He has occasionally employed the open method, and with success, but the tincture of iodine has given such good results that he does not resort to the open operation until the iodine has failed.

Dr. J. Ewing Mears said that he was somewhat surprised at the results presented by Dr. Allis, and was disposed to think ample reasons were given by those who discussed the paper for the want of success and the results that have been reported. Unclean instruments and the failure to hold the canula properly in place, so that the fluid escapes into the connective tissue, are, without doubt, to blame.

He has practised all the methods of treating hydrocele. Formerly it was the custom to inject iodine and allow it to escape, and often the iodine was diluted. Then, principally under the teachings of Professor Agnew, a certain quantity of iodine was introduced and allowed to remain. He has never had untoward results after either method. In his experience the first has occasionally failed, but the second never. He has excised the sac, which is the accepted treatment in chronic hydrocele in which the tunica vaginalis has undergone changes and is much thickened.

There is no operation which he performs with more care, both in hospital and in private cases, than the injection of iodine in the treatment of hydrocele. He prepares the patient, and invariably keeps him in bed a week after the operation. The custom of some surgeons and physicians to inject a hydrocele sac in their offices and send the patient home is dangerous. His own results he believes have been influenced by the care he has taken. He is careful that the canula is clean, and even before the days of antiseptic methods he used hot water and other cleansing methods. Now he uses antiseptic methods in preparing the instruments before operating.

He would hesitate to accept the results reported by Dr. Allis as the results of properly-conducted methods of treatment.

In closing the discussion, Dr. Allis said that he had brought the subject before the Academy because every one in the medical profession is sometimes called upon to operate for hydrocele. His object was to let those who do not practise surgery know that this is a true surgical operation. Many, who would not dare to perform excision or incision, would tap; but he thinks that free incision is a far simpler operation than tapping, and infinitely safer.

In reference to Dr. Porter's case, in which a seton was used, Dr. Allis said that he had reported four cases in which the seton was used in young children. In one of his own cases a child had convulsions with other general symptoms twenty hours after the operation. It could not be determined whether the hydrocele or the seton caused these symptoms, for the child was in the teething period, and recovered from the operation, but he believed that the irritation of the seton had something to do with the symptoms. Dr. S. W. Gross had a case in which alarming reaction followed the use of a single silk thread. Dr. Pilcher, of Brooklyn, lost a case in which a seton had been used for twenty-four hours.

Dr. Allis said that more cases of abscess and sloughing have occurred from this operation than any of us think. The experiences of our hospitals and college clinics would show that the operation of injection is a serious one if we could learn the results. Even the elder Gross had cases of abscess and sloughing after the operation. One surgeon states that he almost had a

death in his office from the injection of carbolic acid. Another states that he has had as much pain from carbolic acid as from iodine. Dr. Packard had said to the speaker: "I wish you would tell us how it is that we have the patient almost dying from the pain, and yet fail to cure the hydrocele." These are matters of common surgical experience.

Dr. Allis accepted all that Dr. Deaver had said. In some of the reported cases the operator states that he made the opening large enough to introduce two or three fingers, but such an incision is entirely too small in a hydrocele the size of a fœtal head. When it collapses it will close such an opening and unless a free incision is made there will be a well of pus to deal with.

In regard to the trocar, he had intended to mention uncleanliness as one cause of the sequelæ. Every one knows that the trocar is *par excellence* an instrument that is difficult to clean. After it is cleaned it should be passed through an alcohol flame, and even then there is reason to distrust it.

It is always a difficult matter to say what the origin of hydrocele is. One writer believes that twenty-five per cent. of the failures are due to disease within the sac, or of the testicle, or epididymitis. If the open method is employed the disease can be seen. No hydrocele should be injected if the fluid drawn off is not of a normal color. If the color is dark or chocolate, some injury has probably occurred, or there is some other disease.

The use of cocaine, original with Dr. Simes, is, doubtless, valuable.

All operations of this character should be done with scrupulous care as to cleanliness.

In conclusion Dr. Allis said that he thought no more important matter could be brought before the medical profession than the treatment of hydrocele.

THE TREATMENT OF TUBERCULOSIS.[1]

By LAWRENCE F. FLICK, M.D.,
OF PHILADELPHIA.

In considering the treatment of tuberculosis it is necessary to keep constantly in view the anatomical construction and the physiological function of the affected part, and the etiology and pathology of the disease. Looking at the subject from these different standpoints the following principles can be laid down:

First. That whatever extraneous matter gets into the system enters through the medium of the blood either by the way of the alimentary canal, by the lymphatic system, or by venous or arterial absorption, and that therefore the bacillus tuberculosis must find its way into the system in this way.

Second. That tuberculosis is strictly a local disease, no matter how many organs or parts may be affected, and that whatever the constitutional symptoms, they are always the result either of interference with the physiological action of some important organ or organs of the body, or of the absorption of some foreign body, the product of tuberculosis, into the system.

Third. That tuberculosis is a specific infectious disease, which can only arise from some other case of tuberculosis, and that when it gets a foothold in any part of the body it can, and probably will, extend to other parts of the body.

Fourth. That tuberculosis has a predilection for those parts or organs of the body in which the circulation is sluggish, as a result either of inactivity of the organ or part, or because of former inflammation.

Fifth. That tuberculosis is always the same disease, whatever part of the body it may affect.

Sixth. That tuberculosis is frequently primarily situated in some unimportant organ of the body, and is overlooked until it affects either the lungs or the brain.

Seventh. That the gravity of the prognosis of tuberculosis is in proportion to the importance of the part of the body affected in carrying on the functions of life.

Eighth. That the improvement and curability of tuberculosis are dependent upon the amount of tubercular deposit, the location, the number of organs or parts implicated, the activity of the parts implicated, and upon the anatomical construction and the anatomical encasement of the organ or part.

Cases of tuberculosis, for the purpose of studying the treatment, can be divided into two classes, namely, those that are accessible to mechanical treatment, such as the use of the knife, caustics, and powerful germicides, and those that are not accessible to such treatment.

The cases of tuberculosis accessible to mechanical treatment are lupus, tuberculosis of the superficial glands, of the cartilages, tendons, joints, and bones, of the perineum and peritoneum, of the vermiform appendix, of the male and female reproductive organs, of the mucous membranes of the mouth, nose, throat, eye, and ear. The treatment of tuberculosis by the knife has at all times been looked upon as a doubtful procedure, and the awe with which it has been regarded by some seems akin to superstition. But this fear, like many of the superstitions of the past, was founded on observation of clinical facts which were inexplicable, but which, in the light of modern research, are easily understood. It was observed that after cutting into tubercular affections general tuberculosis frequently developed, to which the patient rapidly succumbed. We now know that this result is due to the absorption of tubercular matter into the circulation by the cut surface and its deposition in other parts of the body. With our modern knowledge of the infectious nature of tuberculosis it becomes imperative that the knife be not used unless the entire tubercular mass can be re-

[1] Read before the Philadelphia County Medical Society, November 12, 1890.

moved intact, and without reinoculating the patient. This can sometimes be done in tuberculosis of the superficial glands, of the vermiform appendix, of the reproductive organs, of the tendons, cartilages, bones, and joints, and in lupus. In tuberculosis of the accessible mucous membranes and in lupus, caustics and strong germicides are no doubt preferable to the knife. In tuberculosis of the peritoneum washing out and dusting the cavity with iodoform have given good results. It seems to me that where the tubercular deposit is confined to the peritoneum, repeatedly dusting with iodoform might be practised. In tuberculosis of the perineum good results are seldom obtained by the knife, and surgical interference had better not be attempted. Packing the sinuses with iodoform and constitutional treatment will give much more satisfactory results. In tuberculosis of the tonsils caustics are preferable to the knife.

The majority of the cases of tuberculosis come under the second class, namely, those which are inaccessible to mechanical treatment, or in which mechanical treatment is undesirable. For all such cases certain general laws can be laid down:

First. Whatever will sterilize the tubercular deposit without interfering with the nutrition of the body, will cure tuberculosis.

Second. Whatever tends to improve nutrition will help to cure tuberculosis.

Third. Whenever the tubercular deposit sets up excessive inflammation, rest is of primary importance.

The destruction of the bacillus tuberculosis is of course the principle underlying all treatment, whether it be accomplished by medicine or by nature's conservative methods. Throughout the entire civilized world there is at present great activity among medical men in search of a substance which will destroy the bacillus tuberculosis without interfering with the nutrition of the body. That such a substance exists, and will ultimately be discovered, can scarcely be doubted, now that science has indicated to us the way in which to proceed in our investigations. Even at the present time encouraging reports come from our own city, from Germany, and from France, which may soon be followed by the announcement that the discovery has been made. The experiments of Grancher, Martin, Dixon, and Koch, demonstrate that the development of the bacillus tuberculosis can at least be checked in organisms very similar to the human body, and these are the beginnings of a new line of study which may lead up to the discovery of the long-looked-for secret.

We have already in our armamentaria many drugs which will destroy the bacillus tuberculosis, either directly or by depriving it of its nutrition; but they all interfere, more or less, with the nutrition of the body, or destroy the tissues when taken in large enough doses to produce the desired result upon the bacillus. Some of the drugs, however, in safe doses, will enable nature sufficiently to produce a cure. Prominent among the remedies which have been used as germicides in tuberculosis are iodoform, creasote, terebene, sulphuretted hydrogen, carbonic acid, boric acid, arsenic, mercury, tar, ethereal oils, chloride of calcium, salts of gold and silver, iodine, hydrocyanic acid, and the aniline preparations. Each of these has been praised and condemned, but, no doubt, each has merit in its way. My own experience is limited to a few of them, and to these I will confine my remarks.

Iodoform.—If there is any drug in the Pharmacopœia of which I can truthfully say that I believe it has curative powers over tuberculosis, it is iodoform. I have used it in a large number of cases for a period of four or five years, and I am quite sure that I can ascribe to its use improvement in many cases, and cure in not a few. Iodoform acts best in the early stage of the disease, before there is any breaking-down of the deposit, and before the circulation is entirely cut off. It can be given by either the mouth or the bowel, or through the skin. Sometimes it disagrees with the stomach, but just as frequently proves beneficial by preventing fermentation. I usually prescribe the drug in capsules with pepsin, pancreatin, and some bitter extract. When the tubercular deposit is in the pelvis I use the iodoform in the form of suppositories. One of the most effective ways of using the drug, however, is by inunction. I order it in cod-liver oil, in which it is soluble in the proportion of one part in fifteen, and direct that the body be thoroughly rubbed with the solution from half an hour to an hour once or twice a day. The benefits resulting from this method of using iodoform are most striking. I have experimented with the drug hypodermically, but am not as yet ready to make any report as to its use in this way.

Creasote.—Creasote has attracted much attention during the last few years as a specific for tuberculosis, and has been much discussed in the journals. It has been experimentally proved to be an excellent germicide, and has given good results clinically when administered in sufficiently large quantities. There is often difficulty in getting it into the system in large quantities. I myself have never been able to give it with any satisfaction except by inhalation, the drug being volatilized by hot air. In this way I have obtained most excellent results from its use, not, as I believe, by any local action upon the lungs, but through absorption into the blood. A good way to give it is dissolved in some hot liquid. When well diluted it is not so apt to disturb the stomach. Its administration should be begun in small doses,

and gradually increased until very large quantities are taken.

Terebene.—Terebene is very similar in its action to creasote, but is much more pleasant to take. I have given it with advantage by inhalation, volatilized by hot air. It is a good substitute for creasote when the latter drug is decidedly objectionable to the patient.

Boric acid.—Boric acid is such an excellent germicide, and even in large doses is so harmless to the system that theoretically it should be an excellent remedy for tuberculosis. A year ago I gave it a fair trial, but while I saw some benefit from its use, it interfered with digestion to such an extent that I abandoned it. It seemed to be of most benefit in checking fever and night-sweats in the last stages of the disease.

Dr. Grancher, of France, has recently reported a series of experiments and clinical observations bearing upon the use of this drug in tuberculosis, which are quite encouraging. He did not find that it disagreed with the stomach.

Sulphuretted hydrogen.—Sulphuretted hydrogen figured very conspicuously a few years ago as a specific remedy for tuberculosis, but it did not earn for itself a premanent reputation. It was then looked upon as a new remedy, but in reality it had been used nearly a century previously under the name of the "cow-stable cure." Although it has some efficacy its application is so objectionable that it has properly been laid aside.

Carbonic acic, arsenic, mercury, the ethereal oils, chloride of calcium, salts of gold and silver, iodine, hydrocyanic acid, and the many germicide remedies, descriptions of which appear in the medical journals, has each had its champion, but my own experience is too limited with them to enable me to give an opinion. I find excellent use for mercury given at intervals, to prepare the system for other remedies, but I have never used it as a germicide. Arsenic receives great encomiums and no doubt deserves them, but I cannot join in the praises as I am not sure that I have seen any benefit from it. Iodine is a powerful germicide, and all of its preparations are no doubt more or less useful in tuberculosis; iodoform, of which iodine is the active agent, is however probably the best form in which to give the drug. Tar and hydrocyanic acid form the bases for many of the home-cures for consumption, and no doubt possess merit; but as with many of the other drugs mentioned, we probably do not yet know the most efficacious method of administering them.

The stock of germicide remedies for tuberculosis is already quite large and is constantly being added to. It is said that when there are many remedies for a disease there is no cure, but this is more apparent than real. Many roads may lead to a city, but some may take you there more quickly than others, and therefore many remedies may cure a disease but some may do it more speedily than others. Each of the germicide remedies for tuberculosis would no doubt cure the disease, could it be given in large enough doses without injuring the tissues, and some of them do cure the disease in the doses in which they can safely be given. May we not then confidently look forward to the discovery of new remedies in the near future, or methods of applying the old ones, which will always cure the disease, and in a comparatively brief time? Every remedy finds a field of usefulness in the hands of a well-informed, judicious physician; and when to them are added the many adjuvants, in the way of drugs, gymnastics, climate, etc., by which we can aid nature in her efforts to restore and maintain the integrity of the living organism, it can certainly no longer be said that tuberculosis is an incurable disease.

In all living organisms there undoubtedly resides a power to resist parasitic encroachment. In the human body this power has been supposed to reside in the blood and to be exercised by little bodies called phagocytes. Quite recently efforts have been made to impeach the phagocyte, but all seem to agree that the protective power resides in the blood. We certainly do know from clinical observations that in proportion to the excellence of nutrition, which is best indicated by a healthy condition of the blood, the system is capable of obstructing the inroads of disease. This is true of all diseases, but it seems to be especially true of diseases which have a long incubation period and which run a slow course. Persons whose nutrition is at *par* seem to have power to resist tuberculosis under ordinary exposure; and persons who have fallen victims to the disease seem to be able to cast it off or, to resist its encroaches if their digestive and nutritive powers can be readily restored. Upon these two clinical observations much of the classical treatment of tuberculosis was wisely constructed, and whatever germicide remedies may be discovered, improvement in nutrition must always constitute the groundwork of successful treatment.

Inasmuch as the nutrition of the body is so dependent upon the digestive apparatus, the stomach is the first thing to be looked after in the treatment of tuberculosis. If there is any fault in the method of taking food, such as hurried and insufficient mastication, it must be corrected. The nature of the food taken ought to be carefully inquired into, with a view to ascertain whether it is sufficiently nourishing and whether it is suited to the idiosyncrasies of the patient; and if it is not suitable, the proper diet should be prescribed. If it is found that certain

kinds of food cannot be digested by the patient, such foods should be given artificially digested. When the stomach is congested, as indicated by a large, heavily-coated tongue, a light diet should be insisted on and remedies prescribed to relieve the congestion, such as bismuth, bicarbonate of sodium, and magnesia. Small doses of iodoform sometimes act well in such cases. When the stomach and liver are sluggish, usually indicated by a rather pale, indented, slightly-coated tongue, pepsin and hydrochloric acid in some bitter mixture will give good results. When intestinal digestion is bad, pancreatin should be given. As soon as the digestive apparatus has been restored to good working order, forced nutrition should be adopted. Easily-digested food ought to be given at frequent intervals, and every precaution taken against burdening the stomach with indigestible food. All forms of starchy food which have been prepared in such a way as to imbed the starch globules in grease should be scrupulously avoided. Milk should form a large part of the diet, and should be taken at meals, between meals, and at bedtime. If milk disagrees with the stomach, the habit of drinking it can and should be formed by taking a small quantity at first and gradually increasing the amount. By perseverance the stomach can readily be trained to take from five to six pints of milk a day, in addition to one meal of solid food. Meat should be partaken of but once a day, and then in as large quantity as possible. Vegetables and fruit should be freely eaten, and a little light wine at or after meals will be of benefit. Cod-liver oil should be taken, beginning with small quantities and gradually increasing until a tablespoonful three times a day is tolerated, but the greatest care should be exercised that it does not disturb the stomach. The use of oxygen after meals, inhaled slowly for half an hour, will aid digestion and be of great benefit. Quinine, strychnine, and other tonics and stomachics may be given to stimulate the appetite. When the stomach becomes fatigued under this forced labor it should be permitted to rest for a few days, the same regimen being then resumed. During this time of rest it is well to give a dose of calomel, followed by magnesia.

Next in importance to attention to the digestive apparatus of the patient, is to see that he gets plenty of fresh air and the proper amount of exercise. Outdoor life is of the greatest importance, but it does not seem to make much difference where that outdoor life is obtained. The one thing to be kept in the mind of the physician in directing fresh air for his patient is home comforts. Unless the patient can command home comforts, do not send him away. Were every medical student compelled, as part of his education, to make the rounds of the health-resorts of the country on the same amount of money that the average health-seeker has at his command, fewer patients would be sent to health-resorts. Altitude and temperature have less to do with either the production or cure of tuberculosis than is generally supposed. The benefits of altitude can be artificially produced by compressed and rarefied air, and if the patient's mind be relieved from the classical errors about the pernicious influence of cold and moisture, he will be found to do as well in one climate as another, provided he protects himself properly by clothing and has the courage to go out in all kinds of weather. In reality, warm climates are more conducive to the development of tuberculosis than are cold.

Regarding exercise, the physician should be very explicit, as the tendency is to take either too much or too little. Outdoor life and exercise must not be looked upon as synonymous terms. As long as there is a disposition to fever or even to acceleration of the pulse, exercise had better be as nearly passive as possible. Gradually, as the disposition to inflammatory action decreases, and as the various organs of the body begin to perform their functions more normally, exercise may become more active and may be taken in larger amount. At no time, however, must it be carried to the point of fatigue. A good form of exercise is that of driving nails with a light hammer, or, when the patient becomes stronger, that of chopping wood. There is considerable advantage in exercising chiefly with the upper extremities. Pulmonary gymnastics are of great assistance in re-developing an injured lung, but they must not be practised until all disposition to inflammatory action has ceased. Pulmonary gymnastics and excessive exercise during the inflammatory stage are apt to cause the disease to extend, and to make the course of the case much more rapid.

In the acute stage of the disease, when the tubercular deposit sets up an inflammatory condition, bodily rest and remedies that will quiet the excited heart and allay excessive reflex irritation, form an important part of the treatment. During this stage the best place for the patient is in bed. When the tubercular deposit is in the pleura or lung, considerable benefit will be derived from strapping the affected side with adhesive plaster.

Digitalis has a very soothing effect in this stage, and will often contribute considerably to a cure. During the latter part of the eighteenth century it held the reputation among many of the best practitioners in England of being a specific for the disease. Beddoes, who probably saw as many cases of phthisis as any man who ever practised medicine, used the following strong language concerning digitalis in 1803:

"In cases of pulmonary disease, where the presence of tubercle was indicated by every symptom, and where

they seemed ready to break out in open ulcers, I have verified the efficacy of digitalis; and I daily see my patients advancing toward recovery, with so firm a pace that I hope consumption will henceforth be as regularly cured by the foxglove as ague by the Peruvian bark. Could we have a single auxiliary for the foxglove, such as we have many substances for the bark, I should expect that not one case in five would terminate as ninety-nine in a hundred have hitherto terminated."

The only evidence of this great faith in the efficacy of digitalis as a cure for tuberculosis at the present day is found in the confidence still shown in the Niemeyer pill. I have myself used the drug largely in the early stage of the disease for five or six years, and my conviction is that the old faith was founded on correct observation, and that we have in digitalis a most useful remedy for the inflammatory stage of tuberculosis. For the reflex irritation and the resulting symptoms of cough and sometimes of vomiting when the tubercular deposit is in the lungs, and of convulsions and vomiting when the deposit is in the brain or its membranes, opium, bromides, and chloral are the chief remedies. Opium should be used only when it is absolutely indispensable, but when the reflex symptoms are such as to harass the patient, and to interfere with his progress toward recovery, and when no other drug will control them, opium should be unhesitatingly used in quantities large enough to produce the desired effect. In such cases the effect of opium is apparently magical, not only in restoring the confidence of the patient, but in improving his appetite and general condition. As soon as practicable, however, the dose should be decreased and the administration of the drug soon entirely stopped. Where there is bronchial secretion opium should be entirely eschewed. In such cases bromide of ammonium will sometimes act very well. For the reflex symptoms of tubercular deposit in the brain and its membranes, the bromides and chloral are indicated. For the elevation of temperature which is encountered during the inflammatory stage, rest in bed and the administration of digitalis are usually sufficient; but if the temperature is not reduced in a few days quinine, antifebrin, or antipyrine may be given. When the tubercular deposit is in the lung much benefit may be derived by counter-irritation, either in the shape of dry cups, fly-blisters, croton oil, or tartar emetic plaster. In the most acute stage, dry cups are preferable, inasmuch as they can be frequently applied. Fly blisters, whilst painful, are the most powerful external remedy at our command, and are especially useful when the inflammatory condition has reached the subacute stage. They should be repeatedly applied until all evidence of inflammation has disappeared. Croton oil and tartar emetic plaster may be used as substitutes for fly-blister if the patient is too timid to use the latter.

When tuberculosis has reached the stage in which symptoms are caused by the absorption of products of the disease, or because of the interference with the functions of diseased organs, the treatment necessarily becomes symptomatic. For the high temperature of sepsis the administration of large doses of quinine is the safest treatment. Antifebrin and antipyrine are too depressing to be given in this stage. Boric acid given in doses of from ten to fifteen grains every three or four hours is worthy of trial. For the sweats which follow the fever, usually called colliquative night-sweats, belladonna and aromatic sulphuric acid are the standard remedies, and are usually efficient. Agaricin has recently been attracting some attention as an excellent remedy for this condition, but I have had no experience with it. The patient should be cautioned not to use too many bedclothes at night, as sweats are sometimes aggravated thereby. It is also a good plan to sponge the body with warm alcohol.

For the irritative diarrhœa which frequently comes on in the latter stages of tubercular pulmonitis, without any involvement of the intestinal glands, a light, easily-digested diet, and bismuth, bicarbonate of sodium, and pancreatin are indicated. When the diarrhœa is due to tuberculosis of the intestinal glands it will be found difficult to control, but it can be temporarily checked by such astringents as catechu, tannic acid, and acetate of lead. A warm, dry application to the abdomen in the form of a hot bran-bag will be very soothing and beneficial.

The attacks of palpitation which are so distressing and which are apt to come on when there are large cavities in the lungs, I have found are almost instantly relieved by opium and digitalis. Great care must be exercised not to confound this palpitation with the dyspnœa accompanying extensive tubercular deposit and excessive bronchial secretion which it very closely resembles. In the latter conditions oxygen will give relief, and opium must be absolutely avoided. In these cases the reflex symptoms should be met by bromide of ammonium and counter-irritation.

In treating these various symptoms during the latter stages of tuberculosis it must always be borne in mind that they are mere symptoms and not the disease; and that in reality they are often the phenomena accompanying nature's frantic efforts to get rid of a foe. They must never be allowed to assume such a magnitude in the physician's mind as to make him forget his main purpose, namely, to cure the disease.

In conclusion, it may be well to say a word about the methods of medication in the treatment of tuberculosis. The methods usually employed are

inhalation and administration by the mouth. Because of the anatomical construction of the respiratory system and its physiological action, and also because of the pathology of tuberculosis, medication by inhalation is restricted to those substances which exist in or can assume the form of vapor or gas, and which can at once enter the blood by endosmosis or be carried into it through the lymphatic system. Topical applications of remedies to a tubercular lung by way of the respiratory tract are useless, because the tubercular deposit is in the lung-tissue where it cannot be reached except through the circulation. All such plans of treatment, therefore, as the inhalation of hot air as a germicide, and of medicated vapors for their local effect, are based upon misconceptions, and can have no curative influence. Many substances can, however, readily enter the blood through the lungs, and inhalation is an excellent method of administering germicide remedies that can be converted into vapor or gas. The observation has recently been made that chloroform is very destructive to the bacillus tuberculosis, and very good results are reported from the daily inhalation of a small quantity of chloroform. This method of medication is as yet an unexplored field, but it promises well and is worthy of attention.

Medication by the mouth is the method most in use in the treatment of all diseases, and it is the one almost entirely depended on in the treatment of tuberculosis. In giving such substances as have the same physiological and therapeutic effect, in whatever chemical form they are used, medication by the mouth is by far the most convenient and most desirable method. Many substances, however, have different actions in different chemical forms, and with them, however destructive to germs they may be in the test-tube, we cannot know what their germicide and therapeutical powers will be after they have been acted upon by the salivary, gastric, and intestinal juices. It seems to me, therefore, that only such germicides should be administered by the mouth as do not have their therapeutical effect altered by chemical action before reaching the circulation. For drugs whose germicidal powers are changed by chemical action, intravenous injection, hypodermic injection, and inunction offer excellent methods, as in these ways the substances can be brought in contact with the bacillus tuberculosis without undergoing any chemical change. My short experience with inunctions convinces me that they are preferable to giving the drugs by the mouth. The entire question of medication is, however, as yet an open one, and offers an excellent field for clinical observation.

736 Pine Street.

MEDICAL PROGRESS.

Cocaine Anæsthesia Obtained by Means of Cataphoresis.—Dr. Arthur Harries (*Lancet*, October 25, 1890) writes that where local anæsthesia is required, cocaine hydrochlorate, administered by means of cataphoresis instead of hypodermically, should be employed. In a number of cases in which he adopted this method the anæsthesia was complete, and toxic symptoms of the drug were not observed. He uses a ten-per-cent. solution of cocaine, with which the flannel-padded positive electrode, corresponding to the size of the area to be anæsthetized, is saturated. The large negative electrode is soaked in salt solution and placed in a suitable position on the surface of the body. A continuous current of twenty-five milliampères is then passed for forty minutes. Dr. Harries believes that the causes of failure with this method are: That the currents used are too weak, and applied for too brief a time; that the operator does not understand the apparatus; and that a reversed current is used.

The Therapeutic Action of the Sulphate of Cinchonidine.—H. de Brun has recently made an elaborate study of the therapeutic action of the sulphate of cinchonidine in the treatment of the various types of malarial fever. He has carefully observed and recorded fifty-eight cases in private and hospital practice, especially at the Beyreuth Hospital. From the results observed he concludes:

1. That the sulphate of cinchonidine, administered in the amounts in which sulphate of quinine is usually given, is able to prevent the symptoms of paludal poisoning as effectually as the latter remedy. After one or two doses of the first drug the return of the paroxysms of intermittent fever is prevented.

2. The value of the sulphate of cinchonidine in malarial cachexia is doubtful. The drug arrests the destruction of the blood-cell, and rapidly diminishes the general paludal anæmia. It also causes the hæmatin of the blood to increase. It quickly reduces the size of both the congested liver and spleen, but is powerless if the enlargement is due to sclerosis. It also quickly relieves the pulmonary congestions of paludal origin as well as albuminurias dependent upon malarial congestion of the kidneys.

3. It is an excellent remedy in the treatment of intermittent neuralgias, and possibly may prove useful against other neuralgias due to common causes.

4. The sulphate of cinchonidine has often produced beneficial results in those cases where the sulphate of quinine has failed to do any good.

The superiority of the cinchonidine salt is also noticed, in that it is better tolerated by the stomach, and much less apt to produce ringing in the ears and vertigo.

5. The moderate price of the cinchonidine salts is another important consideration.—*Revue de Médecine*, September 10, 1890.

The Use of Sodium Salicylate in Pleural Effusions.—In 1883 Aufrecht recommended the administration of sodium salicylate in all cases of pleural effusion. Tetz (*Therapeutische Monatshefte*, No. 7, 1890), who has used the remedy for two years, states that his success completely confirms the views of Aufrecht. He considers that its

action on pleural effusions is as striking as on rheumatism, and his experience has been that the average time of treatment is less than with other methods. Although it acts most promptly, and certainly in recent cases, he has seen collections of fluid of several weeks' duration yield to it—not only primary but also secondary pleurises. As an example, he reports the case of a woman, about forty years of age, in whom a left-sided pleurisy had existed for two and a half weeks. Ordinary treatment had very little effect, but on the day following the administration of sodium salicylate the effusion had diminished, and all traces disappeared by the fourth day. In another case of long-standing effusion for which paracentesis had been proposed, the use of the drug caused the accumulation to disappear rapidly.

In regard to secondary pleurisy, the author reports a case of tuberculosis with pleural effusion, in which the salicylate also caused rapid subsidence, the diagnosis being confirmed by an autopsy several months later.

Tetz gives the drug in fifteen-grain doses, at first four or five times daily, later three or four times daily for one week. He does not think that the action of the salicylate is that of a diuretic, but that it is a specific.—*Practitioner*, October, 1890.

Salipyrine.—GUTTMANN (*Internationale klinische Rundschau*, September, 1890) reports his results with the use of "salipyrine," a combination of salicylic acid and antipyrine. The compound is a white, odorless powder, with a slight burning taste, freely soluble in alcohol, but almost insoluble in water. Guttmann's conclusions are as follows:

1. Salipyrine reduces elevated temperature. In cases of continued high temperature, a dose of thirty grains should be given, followed by four doses of fifteen grains each, at intervals of an hour. The lowest temperature is reached in about four hours after the last dose, the fall being from 3° to 3½° F. More or less profuse sweating usually accompanies the fall.

2. In acute rheumatism salipyrine is as efficient a remedy as the other compounds of salicylic acid, but has no influence in preventing relapse.

3. In the treatment of chronic articular rheumatism the drug is also useful.

4. Salipyrine rarely produces disagreeable symptoms, even if given for two weeks in daily doses of ninety grains. In but one case was an eruption observed. This resembled the eruption produced by antipyrine, and disappeared in a few days.

5. The color of the urine is not affected by the administration of salipyrine, but the chloride of iron test shows the presence of a salicylate.

6. To reduce temperature, the dose of salipyrine should be twice that of antipyrine.

The Treatment of Partially-amputated Fingers.—ZATVARNITZKY reports the case of a boy who four hours before coming under observation, nearly lost the distal phalanx of his right forefinger by accidentally bringing it in contact with a circular saw. The end of the finger was still attached by a small cutaneous bridge. The author washed the injured part with sublimate solution, arrested hæmorrhage, dusted the wound with iodoform and carefully attached the plalanx to the stump by means of interrupted sutures and adhesive plaster, and applied antiseptic dressings and a splint. Complete union with good motion followed.

In considering such cases the author concludes that if there is much laceration or contusion of the soft tissues or comminution of the bone, union cannot be hoped for; but that if the injury is of the nature of an incised wound union may be obtained, even when several hours have elapsed since the accident, if the amputated part is not very cold and pale.—*Annals of Surgery*, October, 1890.

Disinfection of the Mouth in Diabetes.—DUJARDIN-BEAUMETZ (*Therapeutic Gazette*, October 15, 1890) refers to the fact that the majority of diabetics have a purulent inflammation of the gums, which may be the starting-point of systemic infection, and insists on the importance of disinfecting the mouth in such cases. The solution which has given him the best results for this purpose is the following:

R.—Boric acid	. . . .	6¼ drachms.
Carbolic acid	. . .	15 grains.
Thymol	. . . .	3¼ "
Water	. . . . .	1 quart.

Add to the above:

Spirit of anise	. . .	3½ drachms.
Spirit of peppermint	. .	10 drops.
Alcohol	. . . .	3 ounces.

Cochineal, sufficient to color.—M.

This should be diluted with an equal quantity of water and used freely after eating.

Management of Gonorrhœa.—LANG (*Wiener med. Wochenschrift*, October 2, 1890) discusses some of the causes of the prolongation and complications of gonorrhœa. One of the most important points in the treatment of gonorrhœa is, he thinks, the proper regulation of eating and drinking. In some cases attention to these is all the treatment that is necessary. The injection chiefly used by the author is a solution of sulpho-carbolate of zinc of a strength of from one-fourth to one per cent. Stronger solutions may be employed if a mucilaginous menstruum is used instead of water. It is important to pay attention to the size of the syringe. Patients, if not otherwise instructed, will often use a large syringe, and by injecting too much fluid injure the urethra. Lang uses syringes of three sizes holding respectively, one and a half, two, and three drachms, and to each case orders the size which seems most suitable.—*British Medical Journal*, October 18, 1890.

Ammonium Acetate in the Treatment of Scarlatina.—VIDAL recommends large doses of ammonium acetate in the treatment of scarlatina, and believes that it will also be found useful in the treatment of other exanthemata. In three children suffering from scarlatina to whom he gave the drug in daily amounts of from 35 to 90 grains, the temperature rapidly fell and desquamation was established within four days. In the author's experience the earlier in the course of the disease that the ammonium acetate is given the better are the results.—*Wiener medicinische Presse*, October 5, 1890.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author.

PHILADELPHIA.

SATURDAY, NOVEMBER 15, 1890.

THE TREATMENT OF RECTO-VAGINAL FISTULÆ.

IN *La Médecine Moderne*, October 9, 1890, is an article from the pen of PROFESSOR LE DENTU, the author who not long since gave us an excellent work on the *Surgical Diseases of the Kidneys, Ureters, and Suprarenal Capsules* (Paris, 1889, pp. 828). The occasion of Professor Le Dentu's article is the description of a new method of treating recto-vaginal fistulæ. The method consists of the dissection of a crescent-shaped flap, with its convexity tangent to the lower margin of the fistula, sliding this flap up so as more than to cover the fistula, and attaching its under raw surface to a crescentic denuded area, which includes the fistulous orifice. The sutures are held in place either by segments of a metal tube which, like perforated shot, can be compressed, or by sutures tied over a roll of gauze, in the manner of the old quill sutures.

While admiring the author's ingenuity and appreciating his success in the single case to which the method was applied, we cannot feel that we have here a means less difficult than other methods of treating these troublesome cases, and we believe that there is no treatment for recto-vaginal fistula which will always prove successful.

While we say that there is no *treatment*, we would insist that there are many *treatments*, each of which is excellent and suitable to various classes of case. In other words, we have grouped under the one name *recto-vaginal fistula*, conditions the repair of which may be either the simplest or one of the most difficult of gynæcological procedures.

Fistulæ resulting from cancer and syphilis are, as as rule, beyond the pale of relief, while the remediable cases, those arising from perforation of the recto-vaginal septum by pessaries, by trauma in childbirth, by ulceration, or by an imperfectly-united septum after the perineal operation for complete tear of the septum, present a host of different appearances, according as the fistula is high or low, transverse or longitudinal, large or small, a direct communication through which the rectal mucosa can be seen from the vaginal side, or communicates by a long sinuous track—all these as well as other factors are important and must be weighed, in determining the best plan for attacking a given case of recto-vaginal fistula.

Through the genius of Emmet, Simon, and others we already have a number of rational procedures, sufficient it would seem to cover all cases; thus we can operate upon the fistula through the rectum, or through both the rectum and the vagina, making a bevelled denudation; or, in small direct fistulæ just above the vaginal orifice, the fistulous track may be dissected out through the vagina and closed from the vaginal side alone.

Splitting the perineum and recto-vaginal septum up to the fistula, cutting out the fistulous track and then sewing up the whole wound, has succeeded in some intractable cases situated near the posterior columna. The genius of success and the demon of failure in this work lie, we feel sure, not in the want of a new method which shall simplify—or shall we say complicate—everything, but more in the judgment exercised by the surgeon in his selection of one of the simple methods which we already possess; in the dexterity with which a perfect and even denudation is made; and above all, in the precision with which the sutures are applied—splinting the parts firmly, without constricting them, until the desired union takes place. The surgeon who understands how to use his sutures properly will not need to inject milk into the rectum at the end of the operation to learn if the fistula is closed, nor will he fear that accumulations of gas in the rectum or the passage of fæces will break his line of union.

What we here say of operations upon recto-vagi-

nal fistulæ applies to all plastic operations in the vagina; it is not new methods we are in need of, but more dexterity and greater skill in applying the old methods. Let our surgeons be truly clever workers with their hands.

SOCIETY PROCEEDINGS.

TRI-STATE MEDICAL ASSOCIATION.

Second Annual Meeting, held in Chattanooga, Tenn., October 14, 15, and 16, 1890.

FIRST DAY.—MORNING SESSION.

The Association met in Turner Hall, and was called to order by the President, Dr. J. B. Cowan, of Tullahoma, Tenn., at 10 A. M. Prayer was offered by the Rev. Charles Hyde.

The remainder of the first session was devoted to introductions, miscellaneous business, and reports of the Executive Committee.

AFTERNOON SESSION.

DR. W. P. MCDONALD, of Hill City, Tenn., contributed a paper entitled

REPORT OF A CASE OF CANCRUM ORIS OR GANGRENOUS STOMATITIS.

He was called to see the patient, a girl four years old, on August 5th. She had some fever, the tongue was coated with a brown fur, the surface being more or less fissured, and her general appearance indicated great depression. Her bowels were inclined to be loose, and her abdomen seemed to be somewhat tympanitic. He believed the case to be one of typho-malarial fever, and began treatment by a mercurial purge, which was followed by large doses of quinine and bismuth. This treatment was continued for two days, after which he ordered ten drops of syrup of the iodide of iron after meals, with quinine and bismuth in small doses three or four times a day. This treatment was continued for about ten days, when the patient had greatly improved.

Fourteen days after his first visit he was called to see the patient's mother, whom he found with nearly the same symptoms as those that the child first presented. During his absence from the city, another physician had treated an older daughter, who probably had the same disease. The little child was still improving, but her mouth remained sore. On examining the mother he found several small ulcers on the right side of the mouth, with a general inflammatory appearance of the gums and of the mucous lining of that side of the buccal cavity, with some bleeding from around the teeth. The trouble seemed at first to yield to a mouth-wash of chlorate of potassium and creasote, but on the seventeenth day of the illness the inflammation increased rapidly, the whole cheek became much swollen, and the mucous membrane dark and gangrenous. On August 24th a dark spot about the size of a dime made its appearance externally near the right wing of the nose. This rapidly enlarged, involving the wing of the nose and the adjacent tissues, and on August 25th it had involved the right side of the nose to the inner canthus of the eye and the upper lip to the median line, and had rapidly spread on the cheek, reaching the point at which the zygomatic muscles cross the masseter. Both the upper and lower teeth on this side became loose and dropped out.

Careful investigation revealed a strumous diathesis in the family, but there was no history of tuberculosis.

According to good authorities, cancrum oris usually occurs as the sequel of other diseases. The statistics of Rilliet and Barthez show that out of 98 cases of this disease, 41 followed measles, 5 scarlet fever, 6 whooping-cough, 9 intermittent fever, 9 typhoid fever, and 7 mercurial salivation.

In Dr. McDonald's cases the questions are, Did the disease occur as a sequel of typho-malarial fever, or was it the result of mercurial salivation.

In discussing this paper, DR. E. T. CAMP, of Gadsden, Alabama, said that he had seen a case similar to the one reported, which he pronounced gangrena oris, the whole of one cheek being destroyed. There was evidence of mercury having been taken in the early part of the illness. The case terminated fatally within a few days. The patient was four or five years old and of the lower class.

DR. JAMES E. REEVES, of Chattanooga, contributed a paper entitled

"ON ALL SIDES A LEARNED DOCTOR."

The author introduced his subject by an earnest plea for higher medical education, stigmatizing cheap medical colleges with no facilities for imparting instruction as the greatest stumbling-blocks in the way of true progress.

He referred to the present tendency to make one-sided physicians, and maintained that the specialist should build on the broad foundation of the general practitioner in order to reach professional eminence.

EVENING SESSION.

DR. ANDREW BOYD, of Scottsboro, Alabama, read a paper on

FRACTURE AT THE ELBOW-JOINT,

and reported several cases. He said that after reduction there are but two positions in which to treat fracture at the elbow-joint, viz., the extended or straight, and the flexed position. The author thinks that the flexed position is the better, for the reasons (1) that in all cases there is danger of ankylosis, and it is much better to have a flexed ankylosed arm than a straight one; (2) that after the splints have remained in place from twenty-five to thirty days, the arm is atrophied and almost helpless; (3) that it is easier to overcome the flexor muscles than the extensors, and a patient can extend an arm with more ease than he can flex it.

MR. SYDNEY B. WRIGHT, of Chattanooga, read a paper on

EXPERT TESTIMONY,

of which the following are the most important points:

1. That the circumstances from which the conclusion is drawn should be fully established.

2. That all the facts should be consistent with the hypothesis.

3. That the circumstances should be of a conclusive nature and tendency.

4. That the circumstances should to a moral certainty

exclude every hypothesis but the one propounded to be proved.

5. That mere circumstantial evidence, unless the chain of circumstances is complete, ought in no case to be relied on where direct and positive evidence which might have been given is withheld by the opposite party.

Dr. W. G. Bogart, of Chattanooga, reported a

CASE OF NEUROSIS,

in a girl aged seventeen years. The patient was constipated and had a coated tongue and fœtid breath. Her temperature was 103°; pulse 115. She had been growing more irritable and less communicative, and had suffered from sleeplessness, pain in the back of the head, and a general feeling of depression for several months. She was placed under treatment and seemed to improve. Six months later she was seized with convulsions, and still later she suffered from amenorrhœa.

An interesting feature of the case is that the patient passed three different varieties of worms. A small, black-headed worm, one-half inch long, which had decided vermicular movements; another, with a head like that of a pin; and a third, a small thread-like worm two inches in length.

A paper on

NEURALGIA,

by Dr. W. S. Gahagan, of Chattanooga, was then read by title.

Second Day—Morning Session.

The first paper was read by Dr. J. C. Shepard, of Winchester, Tennessee, and was entitled

A FEW REMARKS ON THE FEVERS OF MIDDLE TENNESSEE AND THEIR TREATMENT.

He said that the great malarial period extended from the time of the settlement of the country up to about 1840, during which time all the fevers of the country were malarial and periodical. The great typhoid period commenced about 1840 and continued until near 1860. During this period malarial fevers were almost, if not entirely, unknown, and typhoid was everywhere dominant and every case was typical. About 1860 there was a return of malarial fever, but in connection with typhoid fever. This was the typho-malarial period, which continued for fifteen or twenty years.

About 1880 the characteristic symptoms both of typhoid and of malarial fevers commenced to disappear, and are still growing less frequent. This is the period of *fusion*. We now have only one fever, which is a continued fever, neither typically typhoid nor malarial, and not even typically typho-malarial. There is not now, and there never was, a continued malarial fever, *per se*, in Middle Tennessee.

Of treatment but little was said. Cold baths the speaker considered impracticable, and new antipyretics should be given with caution. He believed that too much quinine is used in the continued fevers of Middle Tennessee.

Dr. L. P. Barber, of Tracy City, Tennessee, followed with a paper entitled

A CONTRIBUTION TO THE STUDY OF THE CONTINUED FEVERS OF THE SOUTH,

in which he said that the nosology and etiology of the continued fever of the South are now justly attracting much attention, and form a subject upon which much is yet to be learned. Only a close and accurate study of the disease by competent observers, in many and different localities, a thoughtful comparison of these observations, and free discussion, will advance our knowledge of its nature, and shed light on the vexed question of its cause.

Encouraged by the recent vigorous inquiry and research in this direction, Dr. Barber began, some fifteen months since, to keep a record of all cases of fever that occurred in his private practice, and the comparison of the cases has helped him toward a decision as to the nosology of continued fever.

Dr. Barber then reported a large number of interesting cases, after which the two papers on continued fever were discussed.

Dr. G. W. Drake, of Chattanooga, in opening the discussion, said that the human body is an aggregation of cells, and that among these cells are found, in various tissues, certain loose migratory and amœboid cells—phagocytes—which he would call the police force intended to protect the tissues against invasion. When the germs of typhoid fever attack Peyer's patches and the solitary glands, the migratory cells from the adjacent parts, and possibly from distant parts, rush to the conflict. The result is great destruction both of microbes and of phagocytes, and their putrefying remains produce *typhotoxin* and probably other ptomaïnes.

He believed typhoid fever to be produced by germs once external to the body, but expressed a "judicious scepticism" as to whether Eberth's bacillus is the *sole* cause, and its presence absolutely necessary in all cases.

Dr. James E. Reeves said that the malarial influence was undoubtedly slowly, but surely, travelling northward.

Dr. J. A. Long, of Long's Mills, Tennessee, related his experience in McMinn County, Tenn. The fevers there have the symptoms of typhoid fever, but there are many non-typical cases. Some are cases of typhoid in a malarial diathesis. He believed that a few cases of malarial fever continue because quinine is given in too small doses.

Dr. H. Berlin, of Chattanooga, presented some photo-micrographs as an evidence of the existence of microbes in these fevers.

Dr. George A. Baxter, of Chattanooga, suggested the use of salol and naphthol in the treatment of the fevers.

Dr. J. B. Murfree, of Murfreesboro', Tennessee, thought it impossible for two fevers to exist at the same time in one person, and said that there is no typho-malarial fever. We have mild cases of typhoid as well as of other fevers. The use of antiseptics with proper nutrition and stimulation is the proper method of treating typhoid.

Dr. Reeves asked Dr. Murfree if he thought typhoid was contagious.

Dr. Murfree said it was to a certain extent.

Dr. P. D. Sims, of Chattanooga, said: "Our fevers are not all either malarial or typhoid. We have another fever dependent upon filth. It may be called *sewage* or *drainage* fever. It is adynamic in type and is liable to take on most of the symptoms of specific typhoid fever. This is the fever now upon us, arising from the con-

tinued and increasing pollution of our water-supply from sewage sources."

Dr. T. V. Park, of Peavine, Georgia, suggested that as these fevers present the symptoms both of typhoid and of malarial fever, it is convenient to use the term typho-malarial, as we cannot make the public understand the technical points of difference, and we cannot examine our cases for the microörganisms.

Dr. George A. Baxter, of Chattanooga, presented a paper on

SOME NEW USES OF SILICATE OF SODIUM.

The paper chiefly had reference to a jacket made by a new process of hardening the silicate, which it is claimed is an improvement on all other jackets, inclusive of the plaster-of-Paris, leather, woven wire, or watch-spring jackets now in use for the treatment of spinal injuries or disease. It is lighter, equally durable, equally immobile when on, and can be removed at any time and adjusted to any lateral pressure desired.

AFTERNOON SESSION.

Dr. Richard Douglas, of Nashville, contributed a paper on

ABSCESS OF THE LIVER,

which, he said, is the result of absorption of some morbid product from the intestine, or from some ulcerated surface. The bacteria enter the circulation and are deposited in the liver, where an abscess is formed. This may be without a rise of temperature.

Dr. Douglas then reported the following case: Four months after an attack of typhoid fever the patient had a chill, slight pyrexia, and a trace of jaundice, these lasting only a few days. There was a globular swelling in the right hypochondriac region; the only local symptoms of which were dull pain and tenderness. The diagnosis was confirmed by aspiration. A free incision let out eight ounces of inodorous pus, and the patient recovered in four weeks.

Dr. E. E. Kerr, of Chattanooga, reported a

CASE OF GALL-STONES,

and was followed by

Dr. J. B. Murfree, of Murfreesboro', Tennessee, who read a paper on

UTERINE FIBROMA.

A uterine fibroma, he said, is a morbid growth developed within the walls of the uterus, and is composed of muscle-cells, fibro-plastic material, and cellular tissue, and is due to a perversion of nutrition. It is non-malignant and homologous in its structure. Pain, hæmorrhage, rectal and cystic irritation, indigestion, dropsy, and exhaustion are some of its results. The growths may threaten life by hæmorrhage, inflammation, septicæmia, or pressure.

The treatment is divided into four methods: (1) Symptomatic; (2) General (by medicines); (3) Electrolysis, and (4) Operative.

By the first method we simply treat the symptoms as they arise and ward off threatened dangers. Hæmorrhage is the most troublesome symptom, and is best treated by quietude, opiates, etc. The hot douche and the tampon are also useful. The general treatment is by the administration of medicines, which are powerless to cause the absorption of a fibrous tumor, and do no good, except to build up the general system.

Ergot is sometimes given to cause the death and expulsion of the tumor, but the speaker has no confidence in it.

The treatment by electrolysis has met with some success, and is worthy of trial. It is especially adapted to the interstitial variety.

Surgical treatment is resorted to for the permanent relief of uterine fibroma. It consists in the removal of the tumor by traction, torsion, excision, enucleation, excision, écrassement, or hysterectomy. When the tumor projects into the uterine cavity it is best removed by excision. When it is interstitial it should be treated by electrity. When subperitoneal it had better be left alone unless the woman's life is a burden and death is threatened, when it should be removed by abdominal section. Hysterectomy should never be resorted to as an ideal operation, but only as a forlorn hope. But conditions do arise when it is eminently proper and should unhesitatingly be performed.

In discussion Dr. W. H. Wathen, of Louisville, Kentucky, said that the more frequently he opens the pelvis the more often does he find that his diagnosis was not correct. Apostoli's method he considered dangerous in private practice, and to be successful in its application the operator must be the most exclusive of specialists. The tumor may be lessened in size, but there are few, if any, cures. A fibroma should not be interfered with unless it gives trouble.

Dr. Richard Douglas wished to emphasize what Dr. Wathen had said regarding Apostoli's treatment. From observation at his clinics and inquiries in the hospitals in Paris, he had not found any cases that were cured, but he had heard of two cases that died as the result of the treatment, one of these being in the practice of Dr. Keith, of London.

Dr. L. P. Barber, of Tracy City, Tennessee, said that Apostoli's method certainly promises much, notwithstanding the remarks of Drs. Douglas and Wathen. He saw something of the results of the treatment during the past summer, and Dr. Franklin H. Martin, of Chicago, told him that of about 200 cases only three had received no benefit. About fourteen per cent. received temporary benefit, eighty-four per cent. were symptomatically cured, and there were a number of actual cures. Dr. Martin has had no deaths in all his experience with electricity. The result, to the unprejudiced, is certainly in favor of the proper use of electricity.

Dr. Murfree, in closing, said that he felt that much could be accomplished by Apostoli's method.

Dr. W. H. Wathen followed with a paper entitled

LAPAROTOMY *versus* ELECTRICITY IN ECTOPIC PREGNANCY,

in which he said that electricity, the only fœticidal means now recognized as orthodox by physicians who practise destroying the life of the fœtus, without abdominal section, in ectopic pregnancy, is no longer used for this purpose when the pregnancy has continued longer than three and a half or four months, and is seldom used after the third month. At this time the fœtus cannot

be killed except by electro-puncture, and the complications and the deaths consequent upon this practice have been so numerous that the most radical advocates of electricity are afraid to introduce the electrodes into the gestation-sac. The use of electricity in extra-uterine pregnancy is practically confined to the United States, and while it is advocated by men of recognized ability and learning in obstetrics and gynecology, Dr. Wathen believes that very soon it will have no support.

The speaker then entered into an argument in favor of abdominal section, for the difficulty and sometimes the impossibility of diagnosing extra-uterine pregnancy in the early months are so manifest that it would be ridiculous to claim that in all the reported cases pregnancy existed; while in the cases in which the abdomen is opened a positive diagnosis may be made by seeing the embryo, or the chorionic or placental villi. If the embryo or fœtus in an extra-uterine pregnancy is killed by electricity, a more or less diseased condition of the pelvic structures is left that endangers the health or the life of the woman, the dangers usually being increased as pregnancy advances. But if abdominal section is done, there is no obstructed tube or other pathological condition left, and if the woman recovers from the immediate effects of the operation she is entirely cured. Her life is no longer in jeopardy because of the danger of pelvic abscess, sepsis, or exhaustion following an effort to discharge the suppurating contents of the gestation-sac through fistulous tracks into the rectum, vagina, bladder, or through the abdominal walls. If we could eliminate the cases in which there was an error of diagnosis we would find that the mortality from the use of electricity and the bad after-results are far in excess of the mortality from abdominal section in the practice of experienced operators.

(*To be continued.*)

CORRESPONDENCE.

To the Editor of THE MEDICAL NEWS,

SIR: In your issue of October 18th, I notice, with regret, a foot-note to my article on "Acromegaly." The late publication of the paper was due to a misunderstanding on my part, and was not the fault of Dr. Hays.

Yours very truly, J. E. GRAHAM.

TORONTO, October 27, 1890.

NEWS ITEMS.

New York Academy of Medicine.—On November 20th the new building of the New York Academy of Medicine, which has just been completed, will be opened with appropriate ceremonies. Dr. Loomis will give an address of welcome, Dr. E. L. Keyes will deliver the anniversary address on the "New York Academy of Medicine," while Dr. Abraham Jacobi will speak upon the subject of "Our Library." Dr. Billings, Dr. Weir Mitchell, Dr. Fritz, and Dr. Fordyce Barker are also expected to be present and to speak. Invitations have been sent out to many of the prominent men in the different cities of the Union asking them to be present, and the occasion will undoubtedly be one of which both New York and the medical profession throughout the country may be proud.

Dr. Bartholow's Retirement.—Referring to the statement in THE MEDICAL NEWS of November 1st, as to the cause of Dr. Bartholow's retirement from the faculty of the Jefferson Medical College, it affords us pleasure to state that in the resolution of the Board of Trustees the only reason assigned is that his arduous and unremitting labor in the duties of his chair had rendered a period of rest imperatively necessary for him. If permitted, we would be glad to publish the correspondence of the Trustees with Dr. Bartholow, which bears emphatic testimony to the distinguished ability and untiring zeal with which he has for so many years discharged the duties of his position.

Uncertified Deaths in Great Britain.—The assertion was recently made on the floor of the British House of Commons that 15,000 persons die and are buried in Great Britain, each year, without a death-certificate having been given as required by law.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM NOVEMBER 4 TO NOVEMBER 10, 1890.

By direction of the Secretary of War, BASIL NORRIS, *Colonel and Surgeon*, and GEORGE M. STERNBERG, *Major and Surgeon*, are appointed members of a Board of Officers to meet, at the call of the senior officer thereof, in San Francisco, Cal., to examine such officers of the Corps of Engineers as may be ordered before it, with a view of determining their fitness for promotion, as contemplated by the Act of Congress approved October 1, 1890.—Par. 5, *S. O. 261, A. G. O., Washington, D. C.*, November 7, 1890.

By direction of the Secretary of War, CHARLES T. ALEXANDER, *Lieutenant-Colonel and Surgeon*, and JOHNSON V. D. MIDDLETON, *Major and Surgeon*, are appointed members of a Board of Officers to meet, at the call of the senior officer thereof, at the rooms of the Board of Engineers, Army Building, New York City, to examine such officers of the Corps of Engineers as may be ordered before it, with a view of determining their fitness for promotion, as contemplated by the Act of Congress approved October 1, 1890.—Par. 4, *S. O. 261, A. G. O., Washington, D. C.*, November 7, 1890.

By direction of the Acting Secretary of War, leave of absence for four days is granted WILLIAM D. CROSBY, *Captain and Assistant Surgeon.*—Par. 1, *S. O. 259, A. G. O., Washington*, November 5, 1890.

LA GARDE, LOUIS A., *Captain and Assistant Surgeon.*—Is detailed as a member of a Board for duty in connection with the World's Columbian Exposition, and will report by letter to Major Clifton Comly, Ordnance Department, member of the Board of Control and Management of the Government Exhibit to represent the War Department.—Par. 1, *S. O. 260, A. G. O., Washington*, November 6, 1890.

BACHE, DALLAS, *Lieutenant-Colonel, Surgeon, and Medical Director Department of the Platte.*—Is granted leave of absence for one month.—Par. 6, *S. O. 82, Department of the Platte, Omaha, Nebraska*, November 1, 1890.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING NOVEMBER 8, 1890.

EDGAR, J. M., *Passed Assistant Surgeon.*—Ordered to the U. S. S. "San Francisco," November 10, 1890.

SPRATLING, L. W., *Assistant Surgeon.*—Ordered to the U. S. S. "San Francisco," November 10, 1890.

WHITE, CHARLES H., *Medical Inspector.*—Ordered to the U. S. S. "San Francisco," November 10, 1890.

SCOTT, HORACE B., *Passed Assistant Surgeon.*—Placed on the Retired List, October 31, 1890.

ASHBRIDGE, RICHARD, *Passed Assistant Surgeon.*—Surveyed and sent to Hospital, Philadelphia, Pa.

KENNEDY, R. M., *Assistant Surgeon.*—Detached from Navy Yard, League Island, and ordered to the U. S. Training ship "Richmond."

ATLEE, L. W., *Assistant Surgeon.*—Ordered to the Navy Yard, League Island, Pa.

KOCH'S DISCOVERY.

SPECIAL CABLE DISPATCH TO THE MEDICAL NEWS.

A FURTHER COMMUNICATION ON A CURE FOR TUBERCULOSIS.[1]

BY PROFESSOR ROBERT KOCH, M.D.,
OF BERLIN

IN an address delivered before the International Medical Congress I mentioned a remedy which conferred on the animals experimented upon an immunity against inoculation with the tubercle bacillus, and which arrested tuberculous disease. Investigations have now been carried out on human patients, and these form the subject of the following observations. It was originally my intention to complete the research, and especially to gain sufficient experience regarding the application of the remedy in practice, and its production on a large scale before publishing anything on the subject; but in spite of all precautions, so many accounts have reached the public, and in such an exaggerated and distorted form, that it seems imperative, in order to prevent false impressions, to give at once a review of the position of the subject at the present stage of the inquiry. It is true that this review can, under these circumstances, be only brief, and must leave open many important questions.

The investigations have been carried out under my direction by Dr. A. Libbertz and Stabsarzt Dr. E. Pfuhl, and are still in progress. Patients were placed at my disposal by Professor Brieger, from his polyclinic; Dr. W. Levy, from his private surgical clinic; Geheimrath Drs. Fräntzel and Oberstabsarzt Kohler, from the Charite Hospital; and Geheimrath v. Bergmann, from the surgical clinic of the University. I wish to express my thanks to these gentlemen.

As regards the origin and the preparation of the remedy, I am unable to make any statement, as my research is not yet concluded. I reserve this for a future communication.[1]

The remedy is a brownish, transparent liquid, which does not require special care to prevent decomposition. For use, this fluid must be more or less diluted, and the dilutions are liable to undergo

[1] Translated from the original article published in the Deutsche medicinische Wochenschrift, November 14th, 1890.

[1] Doctors wishing to make investigations with the remedy at present, can obtain it from Dr. A. Libbertz, Lueneburger Strasse, 28, Berlin, N. W., who has undertaken the preparation of the remedy with my own and Dr. Pfuhl's coöperation, but I must remark that the quantity prepared at present is but small, and that larger quantities will not be obtainable for some weeks.

decomposition if prepared with distilled water. As bacterial growths soon develop in them they become turbid, and are then unfit for use. To prevent this, the diluted liquid must be sterilized by heat and preserved under a cotton-wool stopper, or, more conveniently, prepared with a one half per cent. solution of phenol.

It would seem, however, that the effect is weakened both by frequent heating and by mixture with phenol solution, and I have therefore always made use of a freshly-prepared solution. Introduced into the stomach the remedy has no effect. In order to obtain a reliable effect it must be injected subcutaneously, and for this purpose we have exclusively used the small syringe suggested by me for bacteriological work. It is furnished with a small India-rubber ball and has no piston. This syringe can easily be kept aseptic by the use of absolute alcohol, and to this we attribute the fact that not a single abscess has been observed in the course of more than a thousand subcutaneous injections.

The place chosen for the injection, after several trials of other places, was the skin of the back between the shoulder-blades and the lumbar region, because here the injection led to the least local reaction—generally none at all, and was almost painless. As regards the effect of the remedy on the human patient, it was clear from the beginning of the research that in one very important particular the human being reacts to the remedy differently from the animal generally used in experiments, namely, the guinea pig. A new proof for the experimenter of the all-important law that experiment on animals is not conclusive, for the human patient proved extraordinarily more sensitive than the guinea-pig. As regards the effect of the remedy, a healthy guinea-pig will bear a subcutaneous injection of 2 cubic centimetres, and even more, of the liquid without being sensibly affected; but in the case of a full-grown healthy man 0.25 cubic centimetre suffices to produce an intense effect. Calculated by the body-weight, one-fifteen-thousandth part of the quantity which has no appreciable effect on the guinea-pig acts powerfully on the human being.

The symptoms arising from an injection of 0.25 cubic centimetre I have observed after an injection made in my own upper arm. They were briefly as follows: three to four hours after the injection there came on pain in the limbs, fatigue, inclination to cough, difficulty of breathing, which speedily increased in the fifth hour, and were unusually violent. A chill followed, which lasted almost a hour. At the same time there were nausea, vomiting, and a rise of body temperature to 39.6° C.

After twelve hours all these symptoms abated, the temperature fell, and on the next day it was normal. A feeling of fatigue and pain in the limbs continued for a few days, and for exactly the same period of time the site of injection remained slightly painful and red. The smallest quantity of the remedy which will affect the healthy human being is about 0.01 cubic centimetre, equal to 1 cubic centimetre of the one-hundredth dilution. As has been proved by numerous experiments, when this dose is used reaction in most people shows itself only by slight pains in the limbs and transient fatigue. A few showed a rise of temperature to about 38° C.

Although the effect of the remedy in equal doses is very different in animals and in human beings, if calculated by body-weight, in some other respects, there is much similarity in the symptoms produced, the most important of these resemblances being the specific action of the remedy on the tuberculous process, the varieties of which I will not here describe. I will make no further reference to its effects on animals, but I will at once turn to its extraordinary action on tuberculosis in human beings. The healthy human being reacts either not at all, or scarcely at all, as we have seen, when 0.01 cubic centimetre is used. The same holds good with regard to patients suffering from diseases other than tuberculosis, as repeated experiments have proved; but the case is very different when the disease is *tuberculosis*. A dose of 0.01 cubic centimetre injected subcutaneously into tuberculous patients causes a severe general reaction as well as a local one.

I gave children aged from two to six years one-tenth of this dose, that is to say, 0.001 cubic centimetre—very delicate children only 0.0005 cubic centimetre—and obtained powerful, but in no way

dangerous, reaction. The general reaction consists in an attack of fever, which usually begins with rigors, and raises the temperature above 39°, often up to 40°, and even 41° C. This is accompanied by pain in the limbs, coughing, great fatigue, and often sickness and vomiting. In several cases a slight icteroid discoloration was observed, and occasionally an eruption like measles on the chest and neck The attack usually begins four to five hours after the injection, and lasts from twelve to fifteen hours. Occasionally it begins later and then runs its course with less intensity.

The patients are very little affected by the attack, and as soon as it is over feel comparatively well, generally better than before. The local reaction can be best observed in cases in which the tuberculous affection is visible; for instance, in cases of lupus, changes take place which show the specific anti-tuberculous action of the remedy to a most surprising degree. A few hours after an injection into the skin of the back—that is, in a spot far removed from the diseased area on the face or elsewhere—the lupus begins to swell and to redden, and this it does generally before the initial rigor. During the fever the swelling and redness increase, and may finally reach a high degree, so that the lupus-tissue becomes brownish and necrotic in places where the growth was sharply defined. We sometimes found a much swollen and brownish spot surrounded by a whitish edge almost one centimetre wide, which again was surrounded by a broad band of bright red.

After the subsidence of the fever the swelling of the lupus-tissue gradually decreases and disappears in about two or three days. The lupus-spots themselves are then covered by a soft deposit, which filters outward and dries in the air. The growth then changes to a crust, which falls off after two or three weeks, and which—sometimes after only one injection—leaves a clean, red cicatrix behind. Generally, however, several injections are required for the complete removal of the lupus-tissue; but of this, more later on. I must mention as a point of special importance that the changes described are exactly confined to the parts of the skin affected with lupus. Even the smallest nodules and those most deeply hidden in the lupus-tissue go through the process and become visible in consequence of the swelling and change of color, whilst the tissue itself in which the lupus-changes have entirely ceased remains unchanged. The observation of a lupus-case treated by the remedy is so instructive, and is necessarily so convincing, that those who wish to make a trial of the remedy should, if possible, begin with a case of lupus.

This specific action of the remedy in these cases is less striking, but is as perceptible to eye and touch as are the local reactions in cases of tuberculosis of the glands, bones, joints, etc. In these cases swelling, increased sensibility, and redness of the superficial parts are observed. The reaction of the internal organs, especially of the lungs, is not at once apparent, unless the increased cough and expectoration of consumptive patients after the first injections be considered as pointing to a local reaction in these cases. The general reaction is dominant; nevertheless, we are justified in assuming that here, too, changes take place similar to those seen in lupus-cases. The symptoms of reaction above described occurred, without exception, in all cases in which a tuberculous process was present in the organism after the use of 0.01 cubic centimetre, and I think I am justified in saying that the remedy will, therefore, in the future, form an indispensable aid to diagnosis.

By its aid we shall be able to diagnose doubtful cases of phthisis; for instance, cases in which it is impossible to obtain certainty as to the nature of the disease by the discovery of bacilli or elastic fibres in the sputum or by physical examination. Affections of the glands, latent tuberculosis of bone, doubtful cases of tuberculosis of the skin, and similar cases will be easily and with certainty recognized. In cases of tuberculosis of the lungs or joints which have been apparently cured we shall be able to make sure whether the disease has really finished its course, and whether there be still some diseased spots from which it might again arise as a flame from a spark hidden by ashes.

Of greater importance, however, than its diagnostic use, is the therapeutic effect of the remedy. In the description of the changes which a subcu-

taneous injection of the remedy produces in portions of the skin affected by lupus, I mentioned that after the subsidence of the swelling and decrease of the redness the lupus-tissue does not return to its original condition, but that it is destroyed to a greater or less extent and disappears. Observation shows that in some parts this result is brought about by the diseased tissue becoming necrotic, even after but one sufficiently large injection, and at a later stage it is thrown off as a dead mass. In other parts a disappearance or, as it were, a necrosis of the tissue, seems to occur, and in such case the injection must be repeated to complete the cure.

In what way this process of cure occurs cannot as yet be stated with certainty, as the necessary histological investigations are not complete; but this much is certain, that there is no question of a destruction of the tubercle bacilli in the tissues, but only that the tissue inclosing the tubercle bacilli is affected by the remedy. Beyond this there is, as is shown by the visible swelling and redness, considerable disturbance of the circulation, and, evidently, in connection therewith, deeply-seated changes in its nutrition which cause the tissue to die more or less quickly and deeply, according to the extent of the action of the remedy. To recapitulate, the remedy does not kill the tubercle bacilli but the tuberculous tissue, and this gives us clearly and definitely the limit that bounds the action of the remedy.

It can influence living tuberculous tissue only, and has no effect on dead tissue; as, for instance, necrotic cheesy masses, necrotic bones, etc., nor has it any effect on tissues made necrotic by the remedy itself. In such masses of dead tissue living tubercle bacilli may possibly still be present, and are either thrown off with the necrosed tissue, or may possibly enter the neighboring and still living tissue under certain circumstances of the therapeutic activity. If the remedy is to be rendered as fruitful as possible this peculiarity in its mode of action must be carefully observed. At first the living tuberculous tissue must be caused to undergo necrosis, and then everything must be done to remove the dead tissue as soon as possible, as, for instance, by surgical interference.

Where this is not possible, and where the organism is unassisted in throwing off the tissue slowly, the endangered living tissue must be protected from fresh incursions of the parasites by continuous applications of the remedy. The fact that the remedy makes tuberculous tissue necrotic and acts only on the living tissue, helps to explain another peculiar characteristic thereof, namely, that it can be given in rapidly-increasing doses. At first sight, this phenomenon would seem to point to the establishment of tolerance, but since it is found that the dose can, in the course of about three weeks, be increased to five hundred times the original amount, tolerance can no longer be accepted as an explanation. As we know of nothing analogous to such a rapid and complete adaptation to an extremely active remedy, the phenomenon must rather be explained in this way, that in the beginning of the treatment there is a good deal of tuberculous living tissue, and that consequently a small amount of the active principle suffices to cause a strong reaction, but by each injection a certain amount of the tissue capable of reacting disappears, and then larger doses are necessary to produce the same amount of reaction as before.

Within limits, a certain degree of habituation may be perceived as soon as the tuberculous patient has been treated with increasing doses, for so soon as the point is reached at which reaction is as feeble as that of a non-tuberculous patient, then it may be assumed that all tuberculous tissue is destroyed. Then the treatment will only have to be continued by slowly-increasing doses and with interruptions in order that the patient may be protected from fresh infections while bacilli are still present in the organism, and whether this conception and the inference that follows from it be correct, the future must show. They were conclusive, as far as I am concerned, in determining the mode of treatment by the remedy which in our investigations was practised in the following manner. To begin with the simplest case—lupus.

In nearly every one of these cases I injected the full dose of 0.01 cubic centimetre from the first. I then allowed the reaction to come to an end, and then, after a week or two, again injected 0.01 cubic centimetre, continuing in the same way until the reaction became weaker and weaker, and then

ceased. In two cases of facial lupus the lupus-spots were thus brought to complete cicatrization by three or four injections; the other lupus-cases improved in proportion to the duration of treatment.

All these patients had been sufferers for many years, having been previously treated unsuccessfully by various therapeutic methods. Glandular, bone, and joint tuberculosis was similarly treated, large doses at long intervals being made use of. The result was the same as in the lupus-cases—namely, a speedy cure in recent and slight cases, slow improvement in severe cases.

The circumstances were somewhat different in phthisical patients, who constituted the largest number of our patients. Patients with decided pulmonary tuberculosis are much more sensitive to the remedy than those with surgical tuberculous affections.

We were obliged to diminish the dose for the phthisical patients, and found that they almost all reacted strongly to 0.002 cubic centimetre, and even to 0.001 cubic centimetre. From this first small dose it was possible to rise more or less quickly to the amount that is well borne by other patients. Our course was generally as follows: an injection of 0.001 cubic centimetre was first given to the phthisical patient, and from this a rise of temperature followed, the same dose being repeated once a day until no reaction could be observed. We then increased the dose to 0.002 cubic centimetre, until this was borne without reaction, and so on, increasing by 0.001, or at most 0.002 to 0.005, cubic centimetre.

This mild course seemed to be imperative in cases in which there was great debility. By this mode of treatment the patient can be brought to tolerate large doses of the remedy with scarcely a rise of temperature. But patients of greater strength were treated from the first partly with larger doses and partly with frequently-repeated doses. Here it seemed that the beneficial results were more quickly obtained. The action of the remedy in cases of phthisis generally showed itself as follows: Cough and expectoration were generally increased a little after the first injection, then grew less and less, and in the most favorable cases entirely disappeared. The expectoration also lost its purulent character and became mucous. As a rule, the number of bacilli decreased only when the expectoration began to present a mucous appearance. They then entirely disappeared, but were again observed occasionally until expectoration completely ceased. Simultaneously the night-sweats ceased, the patients' appearance improved, and they increased in weight within from four to six weeks.

Patients under treatment for the first stage of phthisis were freed from every symptom of disease and might be pronounced cured; patients with cavities not yet too highly developed improved considerably and were almost cured, and only in those whose lungs contained many large cavities could no improvement be proved. Objectively, even in these cases the expectoration decreased and the subjective condition improved. These experiences lead me to suppose that phthisis in the beginning can be cured with certainty by this remedy. This statement requires limitation in so far as at present no conclusive experiences can possibly be brought forward to prove whether the cure is lasting.

Relapses naturally may occur, but it can be assumed that they may be cured as easily and quickly as the first attack. On the other hand, it seems possible that, as in other infectious diseases, patients once cured may retain their immunity; but this, too, for the present, must remain an open question. In part, this may be assumed for other cases, when not too far advanced; but patients with large cavities, who suffer from complications caused, for instance, by the incursion of other pus-forming microörganisms into the cavities or by incurable pathological changes in other organs will probably obtain lasting benefit from the remedy in only exceptional cases. Even such patients, however, were benefited for a time. This seems to prove that in their cases, too, the original tuberculous disease is influenced by the remedy in the same manner as in the other cases, but that we are unable to remove the necrotic masses of tissue with the secondary suppurative processes.

The thought involuntarily suggests itself that relief might possibly be brought to many of these severely-afflicted patients by a combination of this

new therapeutic method with surgical operations (such as the operation for empyæma), or with other curative methods, and here I would earnestly warn people against conventional and indiscriminate application of the remedy in all cases of tuberculosis. The treatment will probably be quite simple in cases in which the beginning of phthisis and simple surgical cases are concerned, but in all other forms of tuberculosis medical art must have full sway by careful individualization and making use of all other auxiliary methods to assist the action of the remedy.

In many cases the decided impression was created that the careful nursing bestowed on the patient had a considerable influence on the result of the treatment, and I am in favor of applying the remedy in proper sanataria as opposed to treatment at home and in the out-patient room. How far the methods of treatment already recognized as curative, such as mountain climate, fresh-air treatment, special diet, etc., may be profitably combined with the new treatment cannot yet be definitely stated, but I believe that these therapeutic methods will also be highly advantageous when combined with the new treatment. In many cases, especially in the convalescent stage, as regards tuberculosis of the brain and larynx, and miliary tuberculosis, we had too little material at our disposal to gain proper experience.

The most important point to be observed in the new treatment is its early application. The próper subjects for treatment are patients in the initial stage of phthisis, for in them the curative action can be most fully shown, and for this reason, too, it cannot be too seriously pointed out that practitioners must in the future be more than ever alive to the importance of diagnosing phthisis in as early a stage as possible. Up to the present time the proof of tubercle bacilli in the sputum was considered more as an interesting point of secondary importance, which, though it made diagnosis more certain, could not help the patient in any way, and which, in consequence, was often neglected.

This I have lately repeatedly had occasion to observe in numerous cases of phthisis, which had generally gone through the hands of several doctors without any examination of the sputum having been made. In the future this must be changed. A doctor who shall neglect to diagnose phthisis in its earliest stage by all methods at his command, especially by examining the sputum, will be guilty of the most serious neglect of his patient, whose life may depend upon the early application of the specific treatment. In consequence, in doubtful cases, medical practitioners must make sure of the presence or absence of tuberculosis, and then only will the new therapeutic method become a blessing to suffering humanity, when all cases of tuberculosis are treated in their earliest stage, and we no longer meet with neglected serious cases forming an inextinguishable source of fresh infections. Finally, I would remark, that I have purposely omitted statistical accounts and descriptions of individual cases, because the medical men who furnished us with patients for our investigations have themselves decided to publish the description of their cases, and I wished my account to be as objective as possible, leaving to them all that is purely personal.

KOCH'S DISCOVERY.

The cablegram which forms this extra edition is one which contains, in all probability, the seed of a discovery the extent of whose fruit cannot be grasped by the human mind, and which bids fair to surpass the triumph of Jenner in his warfare against smallpox. Unlike variola, which occurs in epidemics, the great white plague, consumption, has year after year, with far more fearful results, swept off millions of human beings, until every hamlet and village has learned to speak of it with bated breath.

It is not for us, knowing so little of the true nature of Koch's studies, to decide at this time as to the future of his methods. Not improbably many of the profession may be conservative enough to declare their utter lack of faith in all such work. On the other hand, there is the ever-present need in medicine of sufficient thoughtfulness to avoid following every new idea with feverish haste, and while we can regard the man and his work with pride, it behooves us to reserve our opinions until time discloses the more minute workings of his methods.

It also seems appropriate that the leading medical weeklies of each of the great Anglo-Saxon races, THE MEDICAL NEWS and *British Medical Journal*, should be the first to present this subject in an authoritative manner to their countrymen on the same day that the author publishes his original copy in the *Deutsche medicinische Wochenschrift*.

Removal of the Gall-bladder.—TERRIER (*Bull. de l'Académie de Médecine*) records his second cholecystectomy, both operations being successful. The operation has been performed only five times in France. Dr. Terrier's last patient was a woman aged fifty-years who had suffered from exceedingly severe attacks of hepatic colic for twenty-six years. The liver was enlarged, but the gall bladder could not be felt, and there was no jaundice until just before the operation, when the usual signs of biliary obstruction appeared. As these symptoms were not relieved by the usual remedies and as death seemed probable the abdomen was opened. The incision was made in the right linea semilunaris and the distended gall-bladder easily found. It was adherent to the omentum but was easily detached. About one pint of viscid, almost colorless, fluid was drawn off. A number of calculi were then removed with difficulty, after which the neck of the gall-bladder was ligated and the body and fundus removed. The abdomen was closed in the usual manner, a medium-size drainage-tube being inserted. After the operation a large quantity of bile escaped through the tube and there was much vomiting but the patient made a complete recovery.

M. Terrier thinks that in cases in which the gall-bladder is very large the median incision would be preferable. The separation of the gall-bladder from the liver may be followed by free oozing which can be checked by pressure with a sponge or by the thermo-cautery. Large vessels can be lightly tied.—*British Medical Journal*, October 18, 1870.

Psorospermosis.—DR. BOECK (*Monatshefte f. praktische Dermatologie*, September, 1890) presented the following case of psorospermosis to the Society of Physicians of Christiania. The patient, a man aged forty-seven years, had suffered from the disease for sixteen years. Scattered over nearly the entire surface of the body was an eruption of papules, varying in size from a millet- to a hemp-seed, which were covered with epidermic scales. The case was a typical example of Darier's *psorospermose folliculaire végetante*.

Microscopical preparations were shown in which there were numerous encysted coccidia in the epithelium, especially in the stratum granulosum. Where the process was severe the epidermis became detached from the papillary body in such a measure that only single rows of cells covered the latter. Dr. Boeck also presented to the Society at a subsequent meeting two more cases of the disease, both the patients being sons of the patient mentioned above, evidence in favor of the contagiousness of the disease. The eruption in the sons occupied the same sites as in the father. Dr. Boeck said that the disease, when not of not of too long duration, was amenable to treatment, and that therefore treatment should be commenced early. In one of the recent cases pyrogallic acid ointment was applied with success; in the other case no treatment had been adopted.—*British Medical Journal*, October 18, 1890.

Sunflower in Malarial Fevers.—DR. V. N. ZUBOVITCH (*Vratch*) has administered sunflower to a number of cases of malarial fever. He used the remedy in the form of a tincture of either the fresh flowers or the fresh bark of young stems. To an adult a liqueur-glassful was given three times daily, the administration being continued for two or three days after the complete cessation of the paroxysms. With others, Dr. Zubovitch finds (1) that the sunflower treatment is invariably followed by a complete and permanent cure in from three to ten days, even in inveterate cases in which quinine has utterly failed; (2) that all types of malarial poisoning are equally amenable to this treatment; (3) that during the administration of the sunflower no unpleasant symptoms of the drug are manifested other than occasional profuse night-sweats; (4) that the tincture of the flowers seems to act more quickly than that of the bark.—*St. Louis Medical and Surgical Journal*, November, 1890.

Treatment of Epithelioma of the Face with Acetic Acid.—At a recent meeting of the French Society for Dermatology and Syphilography ARNOZAU reported eight cases of epithelioma of the face commencing in the sebaceous glands, that were treated by local applications of acetic acid. The applications were made with a piece of wood, a glass rod, or, if the disease was extensive, with a brush. In some cases the acid was used every second day; in others, every day; and in still others, several times daily. During the first sittings crystallized acetic acid diluted one-half or two-thirds with water was used; later the pure acid was applied. The treatment causes sharp burning, which, however, is of short duration. The eschar produced by the acid at first adheres closely, then begins to loosen at the edges, and the applications should be continued until the crusts drop off and leave a healthy, granulating surface. The granulations then begin to cicatrize, and finally leave a small scar. The patient can carry out the treatment himself.—*Occidental Medical Times*, November, 1890.

The Removal of Freckles.—The *Pharmaceutical Record* quotes the following prescriptions for removing freckles

R. White precipitate } of each 1 drachm.
Bismuth subnitrate }
Glycerite of starch . . 4 ounces.—M.

Apply every second day.

Or,

R.—Sulphocarbolate of zinc . 1 drachm.
Glycerin . . . . 2 ounces.
Alcohol . . . . 1 ounce.
Orange flower water . . 1½ "
Rose water, sufficient to make 8 ounces.—M.

Apply twice daily.

THE MEDICAL NEWS.

THE LEADING MEDICAL WEEKLY OF AMERICA.

The Medical News to-day presents to its great host of readers a practical illustration of the vast benefits they derive from ideal medical journalism. Modern methods of communication render it possible for a vigilant and complete organization to keep in touch with the most distant centres of medical advance, and possessing both these qualifications, The News publishes to its readers simultaneously with publication in Berlin, the authentic account of what is possibly the greatest discovery yet made or to be made by man. Should this discovery prove to be what the claims and character of Robert Koch warrant the world in believing, the effects on the destinies of mankind are inconceivable. It is the proud position of The Medical News to be the leader in disseminating this intelligence throughout the length and breadth of America, not alone to its own subscribers, but in the interests of humanity to great numbers of accomplished physicians who have not hitherto seen the binding obligation of keeping themselves at all times posted on all that may concern their patients.

Tuberculosis, though the chief scourge of mankind, is only one of a vast number of ailments constantly under study by brilliant men in all parts of the globe, and it is the well-executed duty of The Medical News to keep its readers armed at all points with the latest knowledge for use not only against this, but against all other diseases as well. Such enterprise is only rendered possible by the coöperation of vast numbers of readers, and each new subscriber increases the power of his medical newspaper for doing good to all his fellow-men, and at the same time derives personal benefits vastly disproportionate to the small outlay involved. Such an investment is in the highest sense profitable, bearing weekly dividends each exceeding the principal in quantity of value, and in quality only to be estimated by the benefits conferred by the most enlightened medical science upon present and future generations.

ORIGINAL ARTICLES.

INGUINAL COLOTOMY, WITH THE REPORT OF A CASE.[1]

BY ARCH DIXON, M.D.,
OF HENDERSON, KY

ON June 19, 1890, I was requested by Dr. P. H. Griffin to examine a case of suspected fæcal impaction with consequent obstruction.

The patient, a man, aged twenty-two years, tall and spare, had a previous history of frequent and long-continued attacks of constipation, which yielded to treatment within a short time. On June 12th, Dr. Griffin was called to see him in one of these attacks, and found what he supposed to be a fæcal impaction in the sigmoid flexure. There was intense pain, radiating throughout the abdomen, and most marked in the left inguinal region. The usual remedies were prescribed, but without relief. On June 13th, in addition to calomel followed by castor oil, large enemata of hot water were used, which increased the pain and caused only a small discharge of fæcal matter. Opiates were given and purgatives administered each day with no relief, he having taken on the day previous to my first visit about a pint of castor oil and fully as much Epsom salt. I found him with a pulse of 140, temperature 102°, respiration 36; and with tympanites and general tenderness over the abdomen. Under a careful examination no tumor could be detected, but on passing the finger into the rectum a bulging of the bowel, with a teat-like protuberance extending below the sigmoid flexure, could be felt. The gut was entirely occluded. Dr. Griffin's attention was called to this fact, and colotomy was proposed as the only method of relief. The length of time which had elapsed since the obstruction began, nearly eight days, almost precluded the possibility of recovery, yet I deemed the operation a justifiable one if only to relieve pain. Dr. Griffin concurred in this opinion.

Two hours later, assisted by Drs. John Young Brown, P. H. Griffin, William A. Quinn, and medical student Arch Dixon, Jr., the operation was done. On making the usual incision the small intestine bulged through the opening, but was pushed back and retained by a flat sponge. Two fingers of the right hand were introduced, the rectum found and followed up to the sigmoid flexure, where a distinct tumor could be felt blocking the entire gut. Further examination by breaking adhesions and drawing the tumor through the incision, which had to be slightly enlarged, showed that the obstruction was due to volvulus at the sigmoid flexure. The gut was twisted upon itself and lapped over like the end of a tobacco "twist." Adhesions had formed and were so firm that the lumen of the bowel was entirely destroyed, a solid tumor remaining in its place. The intestine was intensely congested, dark and purple, and near the tumor was almost black. The questions of stitching the colon to the edges of the incision and immediately opening the gut, or of resecting the tumor, closing the rectum, dropping it back into the cavity and stitching the other cut end to the incision, at once presented themselves. At this juncture, in manipulating the tumor and testing the firmness of the adhesions, a slight tear was made in the gut immediately above the tumor, through which a small quantity of liquid fæcal matter escaped. This decided the question. The colon was immediately clamped above and below the tumor (phimosis forceps covered with rubber tubing being used as clamps) about two inches above and one inch and a half below the tumor. The rectal end of the intestine was first cut, its edges were turned in and stitched with Lembert sutures of fine silk, dusted with iodoform, and dropped back into the cavity. The same procedure was followed above, entirely removing the tumor. The cut edges of the colon were carefully stitched to the walls of the incision. Upon removing the clamp there was a gush of liquid fæcal matter through the opening, which continued for a short time. The abdominal cavity was irrigated with hot water through the opening left for the removal of the clamp and sponge, until the water returned clear and pure. The opening was then closed and a pad of iodoform-gauze was placed over the artificial anus, and covered with borated cotton, the dressing being retained by a many-tailed binder, the use of which was suggested by my friend, Dr. L. S. McMurtry. The patient was then put to bed with hot bottles around him.

Reaction was fairly good, and on the next morning the man expressed his thanks for the relief afforded him, he having had no pain since the operation. His condition, however, was not promising. Pulse 140, temperature 100°, and respiration 36. Abdominal tenderness was not marked, but there was a condition of exhaustion, which gradually increased until death took place at 9.50 P.M., June 20th, thirty-one hours after the operation.

In regard to the treatment of this case before I saw it, comment is unnecessary. The questions are, whether under the circumstances, the operation was a justifiable one, and whether resecting the gut, closing the rectal end and dropping it into the

[1] Read before the Mississippi Valley Medical Association, Louisville Ky., October 6, 1890.

cavity, and the formation of an artificial anus at the incision, after the manner of Madelung, were to be preferred to stitching the colon to the walls of the incision and making an immediate opening into the gut without regard to the tumor formed by inflammatory adhesions. Taking everything into consideration, the almost gangrenous condition of the bowel at the site of the obstruction, the tear through which fæcal matter had escaped, the doubt that the wall of the gut would hold the stitches, and the fear of leaving a gangrenous tumor within the cavity, all of which were strong arguments in favor of the graver operation, I feel justified in the course pursued, even if nothing more was accomplished than relieving the patient from the terrible agony which he was suffering.

Some general remarks on the operation of colotomy may not be out of place here, especially as there seems to be a difference of opinion among surgeons in regard to the superiority of the two methods—*lumbar* and *inguinal*.

During the past decade the subject of colotomy, always one of interest, has received much attention from the surgical world. The revival of Littré's operation, so long debarred by the dread of opening the peritoneum, has made it necessary to compare the merits of the extra- (so-called) and intraperitoneal methods. Littré, in 1710, first proposed to open the sigmoid flexure for the relief of imperforate anus in children, but there is a doubt as to his having peformed the operation. At all events, the operation seems to have been forgotten until revived by Pilloré, of Rouen, in 1776, who operated by a different method, opening the cæcum by an incision in the right inguinal region.

In 1796 Callisen suggested an operation whereby the colon might be entered without opening the peritoneal cavity. He experimented on the cadaver and endeavored to expose the bowel where it was not covered by peritoneum, by a vertical incision in the left lumbar region: failing in this, he made an attempt to carry out his idea on the living subject.

To Amussat unquestionably belongs the credit of having first performed the retro-peritoneal operation, which was done upon the right side through a transverse incision, with the result of five successes in six cases.

In this country, Ashmead, of Philadelphia, did a left lumbar retro-peritoneal colotomy in 1842, being unaware at the time of his operation of Callisen's proposal.[1]

Until recently the operation has usually been a combination of the methods of Callisen and Amussat. Like Callisen's, it was done on the left side; and like Amussat's, it was carried out through either a transverse or an obliquely transverse incision. The oblique incision, first recommended by Bryant, is now adopted by most surgeons.

Colotomy may be performed for any condition which obstructs the passage of the fæces through the colon, or under any circumstances in which it is advisable to place the bowel at rest. Obstruction may be produced by various causes, such as cancer of the rectum or sigmoid flexure, or of any other part of the colon; tumors of the peritoneum or of any abdominal organ, pressing on the bowel; volvulus of the sigmoid flexure, of the cæcum or of the ascending colon; and by fæcal accumulations and collections of foreign matter. Colotomy may be called for in cases of incurable ulceration of the bowel, however induced, if we have reason to believe that the irritation caused by the fæces and the movements of the intestinal walls contribute to the continuance of the disease, and also in cases of extreme dilatation, with atony of the colon, giving rise to frequent attacks of obstruction.

As a measure to ward off imminent death, colotomy is required in all cases of obstruction of the colon from whatever cause. For imperforate anus the operation holds a special position. It is intended to prevent impending death, and it may or may not be regarded as a cure for the disease. In many cases it is the first step in the process of cure. In every infant born with imperforate anus an operation in the anal region is first attempted; if this fails, colotomy is performed to prevent death. Later, an attempt may be made to cause the bowel to discharge through the anus. In a few words, it may be said that the indications to operate in any given case depend, in the first place, on the chance which the patient has to recover without operation; and, in the second place, upon the probability of success following the operation. To cases of acute obstruction of the sigmoid flexure, or elsewhere in the intestines, there is practically but one termination—death. No case of volvulus, whether of the large or the small intestine, has as yet been known to recover under purely medicinal treatment. Here, then, the indication is clear enough, as clear, Grieg Smith[1] says, as the indication in a case of bleeding from the carotid artery—operation.

But, in the case reported above, it may be said that while the patient had no chance of recovering without operation, yet there was no probability that success would follow the operation, owing to the length of time that the attack had lasted. But it was no fault of mine that the operation was not done sooner, and at the time of operating it was known that there was little, if any, chance of saving

[1] Greig Smith. Abdominal Surgery, second edition.

[1] Loc. cit.

life, but that relief from the intense pain was certain. It was under such conditions that the operation was proposed and consented to. It accomplished all that I expected, for, from the moment the patient came from under the influence of the anæsthetic until death took place, there was no pain.

Now as to the comparative merits of the two methods of operating. As I have said before, the operation of inguinal colotomy is not new; it was suggested one hundred and eighty years ago, but it was left to modern surgery to simplify the procedure, to lay down fixed rules for its performance, and to carry it almost certainly to a successful issue. The indications for its performance are the same as those for the lumbar method, which I am confident it will supersede. In a recent paper,[1] I find that so good a man as Dr. Mathews, the President of the Mississippi Valley Medical Association, in speaking of colotomy, uses the following language: "It is not the purpose of this paper to discuss the question *pro* or *con*, but it is safe to say, that with English and American surgeons, only one operation —lumbar colotomy—is looked upon as justifiable."

In view of the fact that such surgeons as Treves, Chavasse, Reeve, Kelsey, Cripps, the Allinghams, and others, advocate the *inguinal* in preference to the *lumbar* operation, this statement must be looked upon as rather sweeping. Dr. Mathews further says: "It does not seem at all plausible to say that with any method of operating, as much safety can be had in opening the peritoneum as in not opening it. If antiseptic surgery makes inguinal colotomy so very safe, why is it not logical to say that it also renders the lumbar operation doubly safe as compared with other ways."

Is it true that in the lumbar operation the peritoneum is never opened? On the contrary, is it not true that in a large majority of the cases the peritoneum *is opened?*

H. W. Allingham, Jr., in an interesting paper on the causes of failure to find the colon in the operation of lumbar colotomy, and the way to obviate them,[2] says:

"The difficulties sometimes met in finding the large bowel, and the occasional cases in which serious errors have been made, are known to all; and all will agree that unless one of the longitudinal muscular bands, which are invariably, and only, found in the large intestine, be seen, the intestine should not be opened from the loin. These bands are described as being situated: one on the anterior surface, another along the inner part, and the third at the posterior aspect of the gut. It is this posterior band that is looked for, and generally supposed to be seen when searching for the bowel in the lumbar region. It is thought by some authorities that these bands can be easily detected without opening the peritoneum; but this is not so, except in a very few cases. The author finds, from examination and dissection of over one hundred ascending and descending colons, that the bands are always more easily and distinctly seen when they are covered by the peritoneum, which makes them hard, prominent, and shiny; whereas, when the peritoneum is stripped from them, these characteristics are lost. He admits that in eight cases out of one hundred examined, one or two of these bands could be seen, but not very distinctly, on the posterior part of the intestine, although they were uncovered by peritoneum. When the peritoneum covers only about one-half or two-thirds of the circumference of the gut, it is generally reflected from the gut at the longitudinal bands to the walls of the belly. Thus, unless the peritoneum is stripped off, the bands are not visible. If an attempt is made to expose the longitudinal fibres, the peritoneum, owing to its being so firmly adherent to them, is frequently torn, and the peritoneal cavity opened, perhaps, unknown to the operator. It is argued, in favor of lumbar colotomy, that the large intestine can be reached without opening the abdominal cavity. This, of course, is possible, yet it is much more important to make certain that the large intestine is being opened by first seeing the longitudinal bands. *This, from the anatomical points mentioned, can only be done by opening the peritoneum.*" (Italics are my own.)

Moreover, Mr. Allingham, proves that only by finding the bands can the large intestine be known with certainty in most cases. His conclusions are strengthened by three cases, in which he operated on the right side in the dead subject, it afterward appearing that if he had not looked carefully for the longitudinal bands, the descending portion of the duodenum would have been opened instead of the large intestine, an accident that occasionally happens in operating on the living.

Again, the position of the colon may be an abnormal one. In one hundred cases Treves found it out of its usual position on the right side in twenty-six cases, and in the same number of cases he found it out of its usual position on the left side in thirty-six. In eleven cases out of sixty Allingham found it out of position on the right side, and on the left side in ten out of sixty. Thus the general average of anomalous positions is, on the right side, eighteen and one-third cases, and, on the left side, sixteen and two-thirds out of one hundred. From this it would appear that the normal position of the gut is less common than generally supposed. With the intestine in its normal position, and when a longitudinal band uncovered by peritoneum can be seen, all should go well in the lumbar operation. But when no bands can be seen, the safest distinction between the large and the small intestine is wanting, and in such cases Mr. Allingham considers it more advisable to open the peritoneum and search for a portion of the intestine with longitudinal bands than to run the risk of opening the small intestine under the impression that the peritoneum has not been opened, and that it is the large intestine which is being dealt with. Mr. Allingham further says: "The colon may be entirely surrounded by firmly-

[1] Medical Progress, July, 1890.

[2] Annual of the Universal Medical Sciences, vol. iii., 1889.

adherent peritoneum, and may have a comparatively short mesentery, in which condition it is absolutely impossible to reach it, or to see the longitudinal bands without first opening the peritoneal cavity." The colon was found by Mr. Treves to vary in length on the right side in twenty-six cases out of one hundred, and on the left side in thirty-six cases out of one hundred. Mr. Allingham observed the same variation in forty-nine cases out of sixty on the right side, and in fifty cases out of sixty on the left—a percentage on the right side of eighty-one and two-thirds, and on the left side of eighty-three and one-third. In cases in which the mesentery is very long, the intestine, though it may usually be in the loin, can so change its position that when operating on either side it may lie on the side of the belly opposite to that in which the incision is made. Thus absolute certainty that it is the large, and not the small, intestine, or the stomach, that is to be opened, is imperative. The presence of the appendices epiploicæ may inform the surgeon that he has found the large intestine, but these are not as important as the longitudinal bands, since the appendices may not exist on the piece brought to view. Mr. Allingham does not advocate lumbar colotomy when it is possible to perform inguinal colotomy, for the lumbar is certainly the more difficult operation, the patient runs greater risk, and recovers less quickly, and the after-results are not as satisfactory.

Kelsey says: "Allingham does not emphasize the point which he renders so plain, that when the lumbar operation is performed with these necessary precautions to make sure that the colon is the part opened, it loses its only supposed advantage over the inguinal—the non-interference with the peritoneal cavity."

Mr. Allingham gives the following reasons for thinking inguinal colotomy preferable to lumbar colotomy[1]:

1. The position of the patient is better at the time of operation, for himself, the operator, and the anæsthetist.

2. There is not so much tendency for the gut to fall away from the wound, either at the time of or after the operation.

3. The intestine is easier to find, chiefly because the incision is high. The results of five hundred post-mortem examinations are quoted to verify this statement.

4. The fæces do not pass below the artificial opening if a good spur is made.

5. There is less constitutional disturbance.

6. There is little or no suppuration.

7. The tendency for the opening to contract is not greater.

[1] Annals of Surgery, vol. vii. p. 460.

Chavasse, of Birmingham, advances the following reasons for prefering the inguinal to the lumbar operation: [1]

1. It is readily performed.

2. The patient is easily able to attend to his or her wants in connection with the false anus.

3. The patient is able to lie on his back without discomfort.

4. In malignant disease four or five inches more of the colon are left for the performance of its duties.

5. Being nearer the seat of the disease the operator is able to ascertain, if necessary, the precise limits of the growth.

As a matter of experience, Chavasse states that he has always found that the opening in the sigmoid flexure has been sufficiently remote from the neoplasm not to become implicated during life. Malignant disease of the flexure, except at its juncture with the rectum, is of rare occurrence. Up to the time of writing his paper he had performed inguinal colotomy thirteen times without a death.

Cripps[2] records the results obtained by him in 37 operations, 15 of which were lumbar and 22 inguinal, with 2 deaths, a mortality of more than 5 per cent. The mortality of colotomy has been very great. The analysis of 244 collected cases of lumbar colotomy made by Batt in 1884, gave a mortality of 32 per cent., while the inguinal operation gave a mortality of more than 50 per cent. These statistics, he thought, represented the results up to that period, but they are misleading as an indication of what may be expected of the operation at the present time. Batt regards colotomy as an operation of great delicacy, requiring accurate anatomical knowledge and manipulative skill. The preparation of the patient, the hygienic surroundings, and the subsequent treatment of the wound all demand most careful consideration, and materially influence the result. His chief objections to the lumbar operation are as follows:

1. The absence of sufficient working space between the lower border of the last rib and the crest of the ilium.

2. Difficulty in the identification of the bowel in the limited space, as it is sometimes impossible to recognize the longitudinal bands, and numerous instances are recorded in which the small bowel, the duodenum, or even the stomach has been opened by mistake.

3. In fat or muscular patients, the difficulty owing to the depth of the bowel and its want of mobility, in fixing the colon to the skin without undue tension.

[1] Lancet, February, 1889.

[2] Annual of Universal Medical Sciences, vol. iii., 1890.

4. Abnormal deviations, rendering it impossible to find the bowel by this incision.

5. Inconvenience of the posterior opening for cleanliness and the adjustment of pads.

Inguinal colotomy obviates all these objections by affording a practically unlimited space in front, and an incision through which the bowel can be carefully inspected and identified by its longitudinal bands, by its convoluted surface, and by its appendices epiploicæ. The mobility of the sigmoid flexure and the laxity of the skin prevent the difficulty of fixing the bowel without undue tension. The ease with which thorough exploration of the cavity can be made through the incision removes all difficulties attending the abnormal course of the colon. This method also possesses the advantage of enabling the surgeon to verify the diagnosis by free exploration.

The objections urged against inguinal colotomy are that there is a tendency of the bowel to prolapse, and that it is unsuitable for urgent cases. The first objection can be overcome by drawing down the bowel to its full extent, and the second is believed to be more imaginary than real.

Madelung[1] recommends that the colon be completely cut through; the lower opening being closed and returned, the upper opening being sutured to the skin. At the meeting of the British Medical Association at Leeds, Mr. F. Marsh showed a patient on whom he had performed this operation with a very satisfactory result.

Cripps's operation is performed as follows:[2] The patient having been carefully prepared by a bath and by cleansing of the operative surface, an incision two and a half inches long and one and one-half inches from the anterior-superior spine of the ilium is made across an imaginary line drawn from the anterior-superior spine to the umbilicus (Fig. 1). In order to make the opening somewhat valvular, the skin should be drawn a little inward and the tissues divided until the peritoneum is reached; the peritoneum should then be picked up and incised to nearly the full length of the cutaneous incision. The colon being found, a loop of it is drawn into the wound, and, if loose folds of the sigmoid flexure remain immediately above the opening, it should be drawn down and passed through the fingers into the cavity at the lower angle. When all the gut has passed through the fingers, two provisional ligatures of stout silk are inserted into the longitudinal muscular bands opposite the mesenteric attachment, two inches apart. The bowel is now temporarily returned to the cavity, and the parietal peritoneum is sutured to the skin, on each side of the incision, by two sutures of fine Chinese silk, one and one-half inches apart (Fig. 2), after which the bowel is fixed to the skin and parietal peritoneum by seven or eight fine sutures on each side—the last sutures, one at each angle, crossing from one side to the other in such a manner as to leave two-thirds of the circumference of the bowel external to the sutures. The sutures for the lower side should be passed through the lower longitudinal band, as this is a strong portion of the bowel. Those for the upper portion should be inserted close to the mesenteric attachment (Fig. 3). It is best to pass all of the sutures and then tie them with moderate tension in the order inserted. In urgent cases the bowel can be opened at once; in other cases, the opening may be delayed until the fifth or sixth day, when it is usually found covered with a surprisingly thick layer of lymph.

Fig. 1.

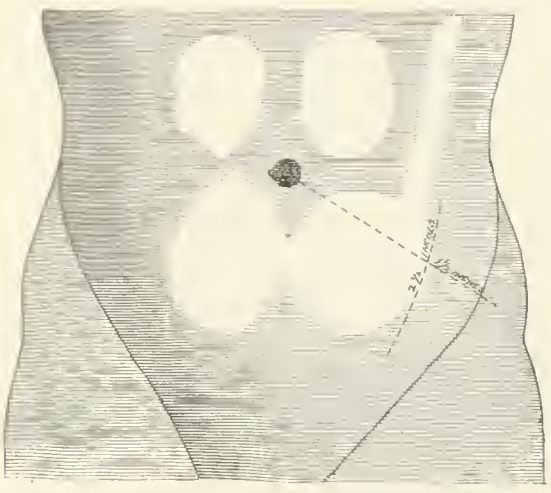

Fig. 2.

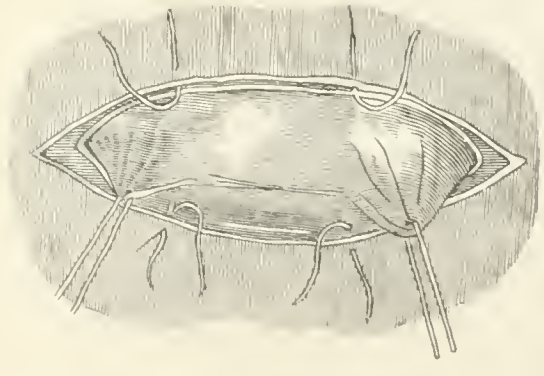


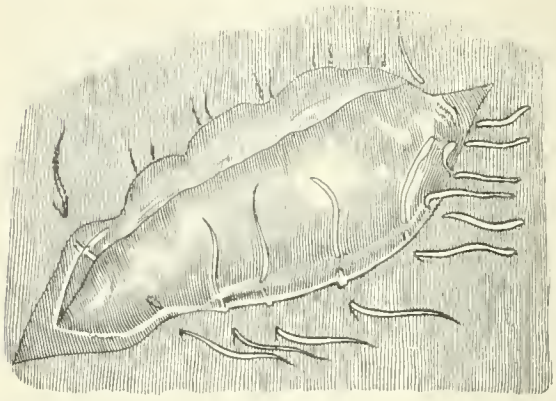
The provisional ligatures will be found useful guides, the bowel being opened the full length between them. The superfluous flaps on either side should be trimmed with scissors to the level of the skin. All sutures may be removed by the ninth day, or earlier if there is redness around them. If the

[1] International Medical Annual, 1890.

[2] British Medical Journal, April, 1890.

bowel is not opened immediately, a piece of protective should be placed over it to prevent adhe-

Fig. 3.



sions of the granulations to the gauze. The wound is then dressed antiseptically, with an additional thick pad and a broad flannel bandage firmly applied. This is important in order to prevent tearing out of the sutures in case vomiting should occur. During vomiting firm pressure upon the wound is of great value.

THE ABUSE OF A GREAT CHARITY.

By GEORGE M. GOULD, M.D.,
OPHTHALMOLOGIST TO THE PHILADELPHIA HOSPITAL.

The abuses of the out-patient departments of many of our city hospitals have become so manifold and so outrageous that public silence is no longer a virtue. Some definitive measure of therapeutics, either social, legislative, or surgical, must at once be devised and made effective.

In brief and in general the facts seem to be something like the following:

The motive in the hearts of the founders and supporters of hospitals was, and is, to aid the deserving poor, who have been visited by the misfortune of disease or physical injury, to have their diseases and wounds healed free of charge by the best medical skill. This must ever remain a most commendable charity, to be deprived of which would be sad for civilization. Few things speak so clearly of the highwater-mark in practical religion and morality reached by the modern world, and it is the unique honor of the medical profession which in this respect no other profession can rival, that this beneficent work is effected by the unselfish and unpaid labor of men who make no claim of merit or show of faith. The burden of this writing is an astounding proof that these noble men have been absurdly generous of their service, and have become the victims of their transcendent unselfishness. What explanation of the abuse under discussion I, or any other, may offer, whatever alloy of baser motives and intermixture of sin may be proved, it will forever remain the glory and honor of medicine, and, indeed, of humanity, that in an age of sordidness and self-seeking so many men have given daily life-long service to humanity without money and without price, with a zeal equalled only by the early Christian missionaries, and with a modest quietness that even they could not rival. These facts may serve to paralyze the finger of shame or scorn pointed at the medical profession by any other, justifying rather a touch of pity at the tangle we have got ourselves into.

In the beginning a distinction should be sharply drawn. Of the in-patient departments, or hospitals proper, nothing disparaging may be said. Barring a few exceptional and curable abuses connected with them, they fulfil their duties with exceptional excellence. But many patients are able to visit the hospital for treatment, and without becoming the recipients of the further charity of bed and board, return at once to their homes and business. Such are called out-patients, and the rooms or departments where the treatment of such patients is carried out constitute the out-patient departments. The physicians and attendants of these departments visit them on specified hours and days, and usually have little or no other relations with the hospital. The out-patient department is thus seen to be an after-thought and outgrowth, sometimes a morbid excrescence upon the body of the true hospital, or in-patient department. When the out-patient is in truth too poor to pay for treatment, or when his disease, if neglected in any way, threatens the welfare of the community, it will at once be conceded that it is the community's right and duty to care for such a patient.

But, with this praiseworthy practice has grown up a most execrable abuse. There has of late been widely circulated a paragraph of some statistician to the effect that in 1889 there were 214,000 charity patients treated in one so-called "pauper city" of the Eastern States. In the great Northern and Central Hospital of England the number of out-patients treated in one year, three years ago, was, in round numbers, 10,000. In 1889 it was 15,563, 3,000 more than during the previous year. According to the *Scotsman*, out of a population of 236,000 in Edinburgh, 103,095 are relieved by medical charities, a percentage of 43. In Glasgow, the proportion is much less, showing that to local custom is largely due the difference in medical pauperization. Mr. Smith claims that in Manchester the abuse of medical charities has been reduced from 42.32 per cent. in 1880 to 6.89 per cent. in 1889. The most conservative medical journal we have, the *Lancet*, says that "everyone admits that the number of hospital patients has grown at a rate fourfold greater than that of the population." In

our country no reliable statistics are at hand, but no one would deny that the *Lancet's* estimate is as low as it possibly could be made. The proportion is probably much greater. It cannot be contended that disease has increased to the same extent, because statistics indubitably prove that diseases are less numerous and less fatal than formerly, and that human life is being lengthened by medical science. We touch the quick and lay bare the root of the trouble when we find that a large proportion, if not a majority, of these hundreds of thousands of charity cases could pay for medical treatment were they not shamelessly pauperized by the unasked gratuity held out to them by these institutions. An innate vice of human nature seems to be the desire to get something without paying for it, and the kind-hearted must always be on the strictest guard that want is real, and suffering not assumed. The degradation of patient and of physician is in full operation, and what was once honorable both to give and receive has become alike dishonorable to receive and to give.

First, as to the patient. Due to the indiscriminating methods of the gift, it is fast becoming a settled conviction that the hospital is in some way a governmental or State institution. Most patients are surprised when told that the physicians who treat them never receive a cent from the city, the State, or from anyone. If told that all hospitals are built and supported by the gifts of kind-hearted people, the service is still considered as one to which they have a perfect right, and arrogant feelings are betrayed by every look, word, and gesture. Gratitude either to the unknown giver or to the physician is rarely shown, though this is frequently if not generally, due to the dictatorial way the patient is treated. To illustrate the manner in which the matter is viewed by the out-patient, I may allude to the case of a woman who had been in a hospital, but who could not afford the loss of time required by the hospital treatment. She did not object to paying me fifteen dollars for the three visits made at my office. The hospital she had gone to was one of the rare examples in which there is even a routine of questioning as to the patient's ability to pay for medical attention. She had been told by her friends to wear her shabbiest clothes, and in answer to any query to aver that she was unable to pay. This she did, and she laughingly added that it was the general custom of her neighbors to proceed in this manner. Every clinician has numberless recollections of similarly ludicrous or disgusting instances of how women come dressed far more richly than the doctor's wife could afford to dress, of absurd pretensions, and innumerable trickeries. That he is but getting his just due the patient learns to believe by the many subtle processes of self deception and cunning whereby men always learn to justify lack of self-dependence. Custom and habit conclude the facile descent to Avernus. "What's the use of paying when we can get it for nothing?" is the unanswerable curbstone logic. No lesson of history and social science is more horribly true than that indiscriminate almsgiving is a crime against God and man, debauching alike both giver and receiver, and multiplying the evil it would thoughtlessly cure. The Roman senators had the mob's dreadful cry, *Panem et Circenses!* in their ears as Rome went to her death, and to our modern demagogic legislation we are adding morbid forms of private charity to teach men loss of self-control and self-help. To free medical advice, free treatment, and free drugs, it is even seriously proposed to add, to the out-patient's ruin, free lunches and free soup.

Not only morally, but medically, the practice has its baneful effect upon the patients. They flock to the hospital in such numbers that the visiting physician has often to treat, or pretend to treat, from thirty to seventy-five per hour. It is the acme of folly and nonsense. "Snap diagnoses" must be made and medicines delivered as if by machinery. Formulæ are kept printed and numbered and are hurried to the druggist, who has the compounds already made and labelled. Upon the appearance of certain symptoms, that might as well be ticketed No. 1, 2, 5, etc., formula 3, 6, or 8 is shot out as if by a nickel-in-the-slot machine, with the exception, of course, of the nickel justice. Every careful physician detests such things, and there is probably some shame in the hearts of everyone who finds himself doing them. A friend told me yesterday that a boy came to him who had made the rounds of several hospitals—there is a large class of folk descriptively termed the "rounders"—and who continuously complained of pain in the side. No other physician had had the time or conscientiousness to examine the boy thoroughly, but had given him salicylates for probable muscular rheumatism. My friend, with some reluctance at the loss of time, quickly had the boy's clothing removed, and at once found curvature of the spine! Possibly this may be an extreme and humiliating example, one not frequently occurring; but every hospital physician will tell you that such examples are entirely too frequent, and that the like may take place many times each day. In almost every case the out-patient cannot get the careful treatment that he should have, and that he would get if the physician's services were paid for. Moreover the patient who can run to the hospital every time he imagines himself to have even the slightest ailment, soon learns to neglect the simplest hygienic rules upon which health depends, quickly falling into habits of self-indulgence, over-reliance upon the doctor, chronic hospitalism, and querulousness.

To the physician, also, the injury is quite as plain. Men spend their early years and their own or parents' savings in laborious study and unflagging zeal to prepare themselves for a life-work that at best is full of arduous duty and toil, that offers no brilliant financial results and demands the best that its devotees can give. When they enter upon their career they find that the older physicians treat, free of charge, thousands and hundreds of thousands of patients who could pay something, and that the younger physicians who need encouragement and practice, and to whom these patients would naturally fall, are left to starve for years, until somehow, by the grace of God, the accidents of chance, or the wiles of scheming, they wriggle into a properly-compensated practice. It is brutally unjust to the young practitioner. It is also as entirely unjust to the suburban and country practitioner, who every day finds that his patients and neighbors have gone to the city hospital and have been treated for nothing. He well knows that he could have treated them more carefully and scientifically at home than the overworked city doctor (perhaps his college classmate) can do in the over-crowded out-patient department. And he knows how able to pay these patients may be. It is highly ungenerous and selfish on the part of those who, having established their practice and feeling financially secure, are able to give an hour or two of each day to treating hundreds of patients without compensation for the poor satisfaction of vanity or to cull from many routine and uninteresting cases one that is rare and "interesting." It is but fair to state that this injustice is unparalleled in any other profession. There are no law hospitals or charity courts where legal advice and counsel may be had for the asking. The young lawyer is not at the outset of professional life met with such an outrageous indignity. Is health worth less to men than property and legal rights? Why should those who give their lives to medicine not be paid for their work?

Several strange and indirect evils result from these crowded out-patient departments. Students and young physicians are taught by conceit, example, and necessity to make hurried, "snap" diagnoses, to treat diseases by memorized prescriptions and the rule of thumb, mechanically, carelessly, and hastily. Every careful physician well knows how fatally unscientific and full of errors such procedures must be. Disease is neither understood nor cured in that manner. Finally, it may be noted that the crowded out-patient room is a bad school of manners. Both ungentleness and ungentlemanliness are almost necessary. A mob of folk have to be handled in a great hurry, and dictatorial manners, harsh commands, and discourtesy are too frequently the result.

How and why has the abuse arisen? It may be accounted for as the combined result of several confluent causes, among which, as has been intimated, must never be forgotten the tender solicitude and unselfish kindness toward the sick on the part of medical men generally. But other reasons are not hard to find. First in importance is the carelessness of almsgivers and testators in failing to demand, and in vigilance to see, that their donations do not become a source of injustice to the medical profession and of corruption to the patient. The physician has never advocated payment for his own services, and the efficacy of the charities of the rich has always been dependent upon the greater charity of the physician. When once the necessity of carefully guarding against this abuse of kindness becomes generally recognized, almsgivers may be relied upon to correct the wrong. Men are kind, and are willing to relieve unmerited and even merited misfortune and suffering, but nothing more quickly shuts the hand and freezes the sympathies than the knowledge that the one you are helping secretly thinks you a fool for doing it, that the method of helping unwittingly increases the evil, and that kindness to one is a greater unkindness to another.

The trustees and managers of hospitals are often largely at fault. Every institution has something in its charter or regulations prohibiting the abuse and guarding against its happening. Subscriptions could hardly have been secured without such an understanding on the part of the donors. But whatever may be said to the contrary, and with some honorable exceptions, it might as well be frankly stated that these rules and regulations are widely ignored. Not one hospital in twenty even asks if the patient is or is not able to pay something for his treatment. And if asked, when the desired and to-be-expected answer in the negative is returned, the investigation is deemed at an end, though the answer is a manifest falsehood. Could human nature, under such circumstances, be expected to resist the temptation to lie? Some far more exhaustive and effective method of getting at the truth than people's own report of themselves has long been recognized as necessary in other forms of charity, and why not in this?

It may strike one as strange, but it is nevertheless a fact, that there is competition among hospitals as furious as it is foolish. The rivalry as to which can do the most good is but a step to that as to which can treat the greatest number of patients. It is a form of the struggle for existence prevalent everywhere, and, as everywhere, it is not always the fittest but the strongest and most unscrupulous that sometimes survives. I have been told that the statistics of hospital reports are by no means always to be trusted. There is a laudable and there is a fool-

ish pride in relieving the poor. The managers and residents must justify their office and their hopeful promises. The "source of supplies" is not averse to entertaining the pleasing thought that he is doing a world of good, and that his gift has not been tied up in a napkin. Such things tend to increase carelessness, indiscrimination, and general sentimentalism. The bidding for patients in the general competition is not seldom frank and unconcealed. The yearly report that shows the greatest number and variety of patients makes the breasts of donor, superintendent, and physician swell with pride and their eyes snap with partisan satisfaction. How easy, under such circumstances, for the abuse to thrive and wax strong.

Sometimes, nay, generally, a "chromo is given with each purchase;" that is to say, most hospitals also dispense medicines without charge. Frequently it is right to do so, but frequently it is mere competition. How can one institution charge even the smallest fee for drugs when its rival does not? It would soon lose its "patrons."

Perhaps the best motive underlying the abuse, and coming the nearest to justifying it, is the desire for "clinical material" for teaching purposes. Hospitals that are not used by medical teachers cannot make this excuse; but they feel the rivalry of those that are so used, and bidding for patients becomes almost a necessity. Schools of medicine must be located in cities where clinical examples of disease are numerous and easy to obtain. Students must see and know disease in order to recognize it in the future in all its forms and to treat it intelligently. Every school of medicine must therefore have its hospital and stimulate its out-patient department to the degree required by this necessity. Whatever may work to this end without too great abuse and too much injustice to others may be conceded as right and necessary. It may even be admitted that a large number of patients must be attracted in order to glean the desired types and illustrative examples of certain diseases. And yet we speedily come to neglected discrimination and unnecessary abuse. For the honor of medicine and of the school there should be in every case attracted a leisurely and careful diagnosis and scientific therapeutics, and such schools should not allow themselves to be drawn into competition with the dispensary and the advertising hospital. There is too frequently an unseemly hunger for the curiosities, the exaggerated anomalies of disease—the "interesting cases." Lecturers are prone to show such cases for teaching purposes. They serve at once to command the students' attention and display the professorial erudition. But there can be no doubt that, for the students' good, the commonest types of disease are precisely those he should see and study most. It is these that he will soonest and oftenest have to treat when in practice; and if he is well prepared the anomalous case will soon classify itself. The most common should be emphasized as the most "interesting."

Yet another source of the evil may be found in the desire of the visiting physician, whether teacher or not, to see a large number of patients, and thus to study disease in its infinite diversity. To this may be added his desire for increased operative skill and dexterity of hand to be gained by much practice, the perfected technique, the lessons to be derived from errors and mistakes, the confidence in self derived from a large experience, and the subtle self-flattery and self-satisfaction in handling large numbers of men and the awful issues of life and death.

And, since the whole truth were better frankly told, another, and possibly most active, though subtle, stimulant of the out-patient abuse is the desire of the chief and his assistant physicians to build up indirectly a private practice. It is well known that no medical man is permitted by the code of professional ethics to advertise. Let it become suspected that a physician is permitting the use of his name by the reporters of the daily papers to spread the knowledge of his skill and the fame of his cures, and at once a blight falls upon him. It is impossible thereafter to rehabilitate his reputation. He has taken a mean advantage of his more honorable brethren, and, as many a doctor who should have been a politician or a stock-broker has learned, medicine is not commercialism or politics. This fact puts the sordid ambitious doctor at a disadvantage in the race for professional fame; but without the strict preservation of this ethical principle, ambitious sordidness would soon gain limitless success and scientific medicine would be at an end. But the fact serves indirectly to multiply the number of the dispensaries and out-patient departments. The older men are in charge of the larger and better institutions, and, of course, "they never resign or die." The younger are handicapped, and, fretting under the fact, they manage to start rival dispensaries. In becoming the head of such a clinical department the visiting physician is able to spread the knowledge of his name through the district whence his patients come, and the practice at his office soon increases. By one means or another charity-patients at the hospital become pay-patients at the private office. The patient loses much time at the hospital, meets unpleasant people, sees unpleasant sights, is barbarously "bossed" about, etc. At the private office it is very different. The hospital becomes a "feeder" to the private practice in more ways than this. I have known it to be frankly admitted that this is the design and

the habit, justification being found for the same in many ways. Whether acknowledged or not, and whether flagrant or subtle, the motive and its execution are all too prevalent. Sentiment—*vulgariter*, "the charity racket"—is "worked" to furnish the financial prerequisites of the undertaking, of which the secondary object alone is the alleviation of human suffering.

By inference I have suggested or alluded to some of the baneful results of the out-patient abuse. In part they may be recapitulated as follows:

1. Encouraging pauperism, dependence, and deceit in a large class of the community already too fatally prone to depend upon the State or charity instead of upon prudence or self-help. This is but one of several reasons that would justify summoning the case before the public as a jury.[1]

2. The abuse, if longer ignored, will soon reach such extreme exaggeration, that when the knowledge of its enormity finally bursts upon the community, all forms of related praiseworthy and necessary charity will be chilled, and the efficiency and usefulness of true hospital work rendered impossible from the lack of funds caused by the disgust of testators and of the charitable, at the misuse of their endowments and the abuse of their kindness.

3. A double injury—first to the patient from a hurried and routine diagnosis and treatment, and secondly to the physician, his science, and his skill, from not patiently studying disease, and not conscientiously applying the proper remedy.

4. The degradation of the profession by turning its practice into a sort of medical "free lunch counter," by encouraging envy and subtle methods of advertising, and by preventing the younger and the country practitioners from rising in their work, and depriving them of their proper *clientèle*. To these things may be added the multiplication and yet deeper abuse of one of the reactions already in full swing in every city, the custom of the doctor to own a drug store, and to give advice and prescriptions free, on condition that the medicine shall be bought at his store.

What is the cure? A number of cures have been proposed, and the following have been, or are being tried:

1. That the competition idea be thoroughly carried out—*à toute outrance*. This means that every practitioner who wishes, or who can, shall rent a room in as conspicuous place as possible—perhaps, get a church to give him the use of one for sentimental reasons, or a drug-store for financial reasons—and advertise to the uttermost the free treatment—and doctor. A beautiful spectacle!

2. The purgatorial plan—a compromise between heaven and hell—that is, out-patient departments where all who are treated are expected to pay something, as little as they must, as much as they will, or with a regular minimum fee of, say, ten to twenty-five cents. A variation of this plan is the medical club formed by a number of members who secure a physician's services at a low club-rate, either per visit or per annum. The design is favorable to the self-respect of the better poor, and gives the attendant some sort of financial justice. It has the excellent advantage of putting the relations of doctor and patient on some basis of mutuality, of encouraging courtesy, and of discouraging slipshod haste and treatment. It is open to the great liability of failure that purgatory itself is subject to—it is neither one thing nor the other. Those lost to self-respect will go elsewhere, and keep their money for beer and ribbons. Those who can pay a little will usually be able to pay a modest fee at the private office.

3. The establishment of charity days or hours at the private office, when all who come will be treated free of charge. This plan is open to all the objections that the hospital abuse suggests, and to many more besides.

4. The sliding scale at the private office, the fee depending upon the patient's circumstances, the lowest honorarium being demanded in the case of the very needy. Willingly or unwillingly, this plan is *de facto* largely pursued, assuring the sensitive poor a desired and desirable protection and privacy, and the kind-hearted advisers a privilege few like to deny themselves.

These four ways pertain to the individual judgment and action of each physician. But, as may readily be divined, the evil will never come to an end by individual action. The abuse is a huge and corporate one, and it has so slowly and blindly drifted to its present low level that only a wide knowledge and a combined harmonious action on the part of many can adjust and remedy it.

It would naturally seem that the pride and honor of the medical profession would spur it to an activity of immediate and effective therapeutics. Just what should or will be the nature of such a remedy no single person would be sufficiently venturesome to say. But assuredly the remedy lies openly in the hands of medical men and medical societies; assuredly one swift word from these sources would

[1] A year ago I gave to the editor of a medical journal, a personal friend, a little article having the same general tenor and purpose as the present one; but he refused to publish it on the ground that the abuse did not exist, and that even if it did exist, I would injure my standing among my professional brothers by calling in the public as witnesses of it. I replied that no one could love my profession better than I, and that the very veneration in which I held it nerved me to brave the possible scorn of a few interested or narrow-minded partisans. There can now be no doubt about the extent of the abuse, even *The Lancet* admitting and deploring it. It will certainly not be cured by ignoring it.

right the whole matter. That, so far, the Profession has made no effort in this direction, and that it so commonly denies the fact of the abuse, argues ill for its self-healing power. A fatal anæsthesia seems to characterize as well as mask the symptoms of the disease. The successful practitioner is satisfied with the *status præsens*, the unsuccessful is afraid or powerless. In the meantime the disease grows visibly worse. The sting in the sneer, *Physician, heal thyself!* has lost its hurt. It is well known that when ill a physician never treats himself, but calls in a brother practitioner. Perhaps, also, the rule would work well in the case now in hand. If so, and while awaiting a more concerted and effective method of therapeutics, it might not be amiss to prescribe a general prophylactic measure, a codicil to all wills and bequests running somewhat as follows:

"And I further direct that the fact of the acceptance of the stated moneys, bequests, and gifts, by the trustees of the above-mentioned hospitals, dispensaries, and charitable institutions, shall of itself be the warrant and guarantee upon their parts of a solemn promise that no patient shall receive medical treatment, advice, or medicines within or under authority of the same, who does not bring proof of his poverty and of his deserving from the Charity Organization Society, or who in some other equally certain and convincing way does not demonstrate that he is unable to pay for such medical advice, treatment, and medicines. And I further direct my heirs and executors to withhold the payment of all such bequests and gifts from those institutions whose trustees will not enter into such an agreement, or from such as may at any future time fail to carry out such agreement, or who, in any way, fail to exercise the most stringent care that the sick who receive the benefit of this bounty shall be needy, deserving, and worthy persons, the subjects of misfortune not by their own gross crime or fault."

Postscript.—Since the above was written, and just as it was sent to the printer, the *Lancet*, in a leading editorial, attacks the abuse, using much the same arguments as I have advanced. It says, *inter alia*: "The absence of any effective inquiry into the fitness of patients is monstrous. What would be thought of a poor-law system which gave relief without inquiry? It would be denounced as immoral and demoralizing. It is not otherwise with voluntary charities. . . . Much efficiency may be dearly bought at the expense of the medical profession in the first place, and of the demoralization of the poor in the second. The wide disapproval of it has been too long disregarded by hospital governors, and we fear we must add, to some extent by medical teachers."

TREATMENT OF INFANTILE CLUB-FOOT PRELIMINARY TO OPERATION.[1]

BY F. H. MILLIKEN, M.D.
OF PHILADELPHIA.

THE purpose of this paper is to offer some suggestions regarding the treatment to be used in cases of club-foot before proceeding with the final operations of tenotomy and osteotomy. Not infrequently we hear of tenotomy, and even of osteotomy, being performed on the feet of infants not more than two or three months old. This is premature practice, and is attended with disadvantages which result from the fact that the muscles of the feet have not been used.

In a congenital, or in an early acquired case of talipes, the bones, tendons, and ligaments are distorted and displaced, and although tenotomy may be performed, and the feet twisted into their normal position, yet, as the members do not assume their proper functions until the child walks, it must remain for many months an open question whether a further resort to the knife may not be necessary. Although success is attained by careful surgeons who personally supervise the subsequent manipulative and mechanical treatment of these cases, it cannot be denied that relapses are more frequent among very young infants than among older ones who received surgical assistance at about the time they began to use their feet and legs.

The fact that a relapsed case of talipes is always difficult to correct should make us hesitate to perform a cutting operation until other and simpler means have been tried, but if resort to the knife is the only alternative, the operation should be performed at the age when the child would begin its efforts to walk. Although it is advisable to postpone cutting operations until near this time, other means should not be neglected, and, if possible, the child should be helped to use its limbs properly without any operation.

Happily, malformation of the limbs is readily recognized at birth, and no time need be lost in using such means as the surgeon may decide on as most suitable to the case, preliminary to the probable final resort—tenotomy.

At birth the tissues are soft and yielding, and with slight manual force can be helped into their proper places. A case of slight talipes can be relieved by daily manipulations, while the same case, if left to itself for several months, would have a tendency to permanent malformation. Owing to this condition, the machinery of the limb being thrown out of gear, the natural coöperative action of the different mechanical parts being altered, permanent lameness and deformity are established.

[1] Read before the American Orthopædic Association, Philadelphia, September 19, 1890.

Perhaps no better means could be suggested for correcting a case of infantile talipes than holding the child's foot in the correct position until a cure is accomplished. But, as in the nature of things, this is impracticable, the next best course must be adopted. The nurse must be *instructed* to manipulate the foot ten or twenty times a day, bringing it into a correct, or as nearly as possible correct position. Emphasis is placed upon the word *instructed*. It will not do to let the nurse merely see the surgeon manipulate the foot and then imitate the procedure as best she can. The surgeon must see that she understands how to grasp the child's foot, and that she knows in what direction to apply the force. A nurse lacking intelligence enough to understand the surgeon's directions is worse than useless, as illustrated by the following case:

A child under my care suffered from equino-varus with incurvation of the toes. The nurse was instructed to grasp the heel and ankle firmly with her left hand, and the anterior portion of the foot with her right hand. She was shown how to correct the incurvation, and by continuing the force bring the foot into a condition of valgus, if possible. In endeavoring to carry out the instructions, the woman grasped the child's leg above the ankle, took hold of the foot and gave it a wrench that bade fair to rupture the deltoid ligament.

In addition to manipulating the foot, the muscles that control it should not be neglected. Massage and the faradic current should be applied, and here, also, the surgeon must be vigilant to see that his directions have been faithfully carried out. Simple instructions to rub and knead certain parts are likely to be neglected, but if a liniment is ordered with which to do the rubbing, the nurse or mother will use it, and by noticing from day to day the diminution in the quantity of the liniment, the surgeon learns whether the rubbing is done.

Very little dependence can be placed on mothers to aid us in correcting the deformed feet of their children. The child's cries excite sympathy, and hence the manipulations are either abandoned, or are so gently performed as to be of little practical value. In view of this fact mechanical means must be employed to stretch the contracted tissues, and, after stretching, to retain the foot in the corrected position. Perhaps the simplest and most efficient appliance for this purpose is a plaster-of-Paris bandage. In the dispensary of the Hospital of the University of Pennsylvania, nothing has given so much satisfaction, among infants under the age of one year, as the following method of treatment:

First, we stretch to the utmost tension consistent with safety, the contracted tissues which are holding the foot in malposition. This is effected by a succession of efforts, using a sufficient amount of force to draw and adjust the parts to the desired position, and then easing off the strain, and repeating it again and again. Continuous tension would probably injure the tissues and prove less efficient.

The tolerance of the feet to the application of force is remarkable. I have frequently felt the tissues tear, and have heard them snap under my hands during my efforts to correct a deformity. This tolerance is most apparent in cases of obstinate and relapsed talipes, in which it is necessary to use powerful levers and wrenches to accomplish the desired result.

After correcting the deformity as far as is possible, by stretching and adjusting the parts, prominent points should be protected by pads of cotton, over which a flannel roller should be smoothly applied. Care must be taken to avoid creases and reverses in applying the flannel bandage, otherwise troublesome sloughs are likely to follow, necessitating an abandonment of the treatment for a time, or the substitution of another dressing. The same caution is applicable in making the first turns of the plaster bandage.

In applying the plaster bandage the turns should be made with a view to correct the deformity by making traction on the roller, *e. g.*, in a case of equino-varus, the bandage should begin at the external malleolus, run diagonally across the top of the foot to the ball of the great toe, thence under the sole to the little toe, and then with a long sweep to the middle third of the leg. This may be repeated until the entire leg and a portion of the thigh are covered. The knee should be bent, otherwise the child is liable to kick the bandage off. The greatest care should be exercised to hold the foot in a correct position while the plaster is setting. It should not be grasped by the hand, as the fingers leave indentations in the soft plaster, and these, when dry, are liable to cause sloughs by pressure on the delicate skin. The palm of the hand should be applied to the sole of the foot, and pressure should be made in a direction opposite to that of the deformity.

Hahn recommends a method by which the foot may be held in a corrected position while the plaster is hardening. One or two layers of plaster are first applied, when the cross-piece of a T-shaped board is placed on the sole of the foot, the ends extending beyond the heel and the toes. The upright of the T projects from the side of the foot. Several turns of the bandage are then made to cover and secure the board. A powerful lever is thus obtained. When the plaster has sufficiently hardened the projecting ends of the T may be removed by means of a saw. I have never used this method, but it seems an efficient one.

Bradford and Lovett in their excellent work recommend that the plaster dressing be renewed

every two or three weeks. This, I do not think is often enough. Renewal once a week, or every ten days, gives the surgeon more work, but better results. When the dressing is removed it is advisable to wash the limb with soap and water, and then to rub it vigorously with alcohol, or better still, with fluid extract of hamamelis. Before re-incasing the foot in plaster the deformity must be still further reduced, and this treatment should be practised at each subsequent dressing. A decided improvement of the position of the foot will soon be apparent if the manipulations are properly performed, and more especially if the surgeon be not too timid to use sufficient force to bring the parts into their normal position.

The plaster-of-Paris dressing has been almost universally described as cumbersome, awkward, and unsightly. The criticism is just if the foot is encased in roll after roll of the plaster, but this is not necessary. My own practice is to use a bandage one and a half inches wide. Three, or at most four, layers for the foot, and three for the leg, are sufficient to hold the most obstinate foot in the corrected position. Over this a woollen legging or a stocking may be drawn. The toes should be exposed, thus enabling the mother to note any change in their appearance. If they become cold, or blue, the dressing should be removed at once, but this will not be necessary if the plaster is properly applied.

The plaster dressing is preferable to apparatus that correct the deformity by means of straps, for the reason that the pressure is made on the entire foot, whereas, in the Scarpa shoe, and in others made on the same principle, traction is almost entirely confined to straps. These are liable to cause excoriations at the points of contact with the skin, necessitating the removal of the apparatus. Valuable time is thus lost. The only disadvantages in the use of plaster are that electricity, massage, and friction cannot be also employed. It has an advantage, however, possessed by no other appliance —that of not being tampered with or removed by the parents of the child.

Elastic traction is employed in cases of club-foot to aid the weaker muscles, and as a constant force tending to pull the deformed members into place. The well-known apparatus of Barwell may be used, but is objectionable because the urine of the child is liable to soak the dressing. The same principle is carried out by Sayre's shoe, which consists of an ordinary laced shoe, in which the "upper" is replaced by a ball-and-socket joint. This leaves the front of the shoe free to be acted upon by force. Two steel uprights extend from the heel to the upper third of the leg. An elastic strap is attached to the sole of the shoe and extends to a button which is riveted to one or other of the uprights near the knee.

Dr. Willard has introduced a shoe that is equally efficient and less expensive. Instead of a ball-and-socket joint, the shank consists of a piece of thin sole-leather, or of soft "upper" leather, thus permitting free movement in every direction. The brace used with this shoe is an improvement on the simple uprights. Greater leverage is obtained by means of a steel arm which is riveted to the stirrup of the uprights. This arm extends forward, upward, and outward, and has an eye at its free end. Through this eye runs a catgut cord, fastened below to the sole of the shoe, opposite the head of the metatarsal bone, and above it to a piece of elastic webbing. The apparatus is especially useful in cases of varus with incurvation. Another very simple and efficient apparatus, also introduced by Dr. Willard, consists of two pieces of printer's blanket, an elastic band, and two ordinary shoe-strings. The printer's blanket should be from two to three inches in width, and sufficiently long to encircle the foot, and the leg above the calf. The ends of the blanket are pierced with eyes, or lace hooks may be substituted, and the two pieces are laced to the foot and leg with the gum-side next to the skin. The elastic band is then fastened to the laces and stretched between the pieces of blanket. The strength of the bands should be adapted to the requirements of the case. The advantages possessed by this simple dressing are, that owing to the adhesive property of the gum it does not readily slip, and need not be so tightly laced as to interfere with the circulation of the blood. It does not absorb urine or fæces, or cause excoriation of the skin, and can be frequently washed without injury. Best of all, it permits manipulation and the use of electricity without disturbing the dressing. An ordinary shoe can be worn with this dressing, thus concealing it, a point which many mothers appreciate.

In private practice, and among people possessing a fair amount of intelligence, the traction principle is by far the best method of treating infantile club-foot; but in dispensary practice we meet with a different class. Here the directions are not faithfully carried out, and the cases often show little improvement. For this reason the fixed dressing is preferable for dispensary cases.

But neither the fixed dressing nor any other can be entirely depended upon to correct a case of severe club-foot, or to effect a permanent cure without a final resort to the knife. What is here advocated is preliminary treatment only. When the child shows an inclination to walk the proper time has come to perform tenotomy, and then the advantages of the previous treatment will be apparent. The plantar fascia will not require such extensive division; the divided ends of the tendons will not separate so widely, and the deformity can be reduced

with comparatively slight force. Besides, with ordinary care there is no fear of a relapse, and the child will be equipped with a more efficient foot than it would have possessed had tenotomy been resorted to earlier.

RACIAL INFLUENCE IN THE ETIOLOGY OF TRACHOMA.[1]

By SWAN M. BURNETT, M.D., Ph.D.,
PROFESSOR OF OPHTHALMOLOGY AND OTOLOGY IN GEORGETOWN UNIVERSITY, OPHTHALMIC AND AURAL SURGEON TO THE GARFIELD AND TO THE PROVIDENCE HOSPITALS, DIRECTOR OF THE EYE AND EAR CLINIC AT THE CENTRAL DISPENSARY AND EMERGENCY HOSPITAL, PRESIDENT OF THE MEDICAL SOCIETY OF THE DISTRICT OF COLUMBIA,
WASHINGTON, D. C.

No apology is needed to practical ophthalmologists for bringing forward even the most insignificant suggestion as to the nature, etiology, or treatment of so intractable and disastrous a malady as trachoma; and the Committee of Arrangements of the Section of Ophthalmology of the International Congress but echoed this sentiment that prevails among the profession in making trachoma one of the principal themes of discussion. Vast as is the literature upon the subject, there is still lacking that which gives us grounds for positive opinions regarding the cause, pathology, and therapeutics of the disease.

The special point that I wish to emphasize and to which I would direct the careful attention of the profession is the essentially dyscrasic nature of the affection. This feature of trachoma seems to have been almost ignored by the majority of those who have dealt with the subject. The oversight can probably be accounted for by the great impetus given to the study of pathological anatomy in all its ramifications within the last three decades, and which has temporarily obscured that larger and more comprehensive view obtained by a study of the disease from the standpoint of its clinical manifestations and its natural history.

We have had many sections of the trachomatous conjunctiva, and bacteriological investigations without number, and yet it cannot be said that there is anything approaching unanimity of opinion as to the pathology or treatment of a disease which, probably next to ophthalmia neonatorum, produces more blindness than any other affection to which the eye is liable.

It is far from my purpose to intimate that these investigations have been valueless. Besides the accurate and positive information that they have given us as to the changes in the conjunctival tissue as a result of the disease, they have had, I think, the negative value of causing us to look outside of the eye for the original cause of the affection.

Trachoma is generally admitted to be an affection *sui generis*. Its course, and particularly its results, are such as are found in no other inflammatory affection of the conjunctiva. The total destruction of the mucous membrane and its conversion into cicatricial tissue are consequences that follow no other inflammation, no matter how severe or how long continued, except, probably, tubercular inflammation. In its course, behavior, and results the dyscrasia bears a stronger resemblance to tuberculosis than to any other morbid process of which we have knowledge, and that great clinician, v. Arlt, in 1854, first noticed the similarity of the two diseases.

Among the more recent changes of opinion, however, toward a wider conception of the nature of the morbid process, was the study of the geographical distribution of the disease by Dr. Chibret,[1] who honored the Congress with a contribution on the subject. The investigation of Farrovelli and Gazzaniga[2] on the geographical distribution of trachoma in the Province of Pavia, and those just published by Reisinger[3] on its distribution in Bohemia, are confirmatory in a general way of the results obtained by Chibret, who found that an altitude of one thousand feet gave a comparative freedom from the disease, and facilitated its cure when present. Other minor contributions from competent persons have confirmed these observations.

At the meeting of the International Ophthalmological Congress, held in New York in 1876, I called attention, for the first time, to the fact that the negro race in the United States seems to enjoy an immunity from trachoma. Further and careful observation among a large negro population since then have confirmed that statement in full. The material of my clinic in Washington is largely composed of negroes either pure or of mixed blood, and among about 6000 cases of eye-disease available for statistical purposes in that race which I have examined, I found but a single instance of genuine, unmistakable trachoma, and three or four of doubtful character. Occasional cases of this disease have undoubtedly been seen in negroes in America, but the experience of such careful observers as White, of Richmond, Va.; Chisolm, of Baltimore; Baldwin, of Alabama, and many others who have spoken to me verbally on the subject, is in all essential particulars in accord with my own.

This immunity cannot be attributed to elevation, since all the places mentioned are at or near the sea level; nor to good hygienic surroundings, for the negroes, with the exception of some of the better class, live in over-crowded rooms, with every possible

[1] Read before the Ophthalmological Section of the Tenth International Medical Congress, held in Berlin, August 3–9, 1890.

[1] Comp. Rend. Copenhagen Congress, 1884.

[3] Graefe's Archiv, B. xxxvi., Ab. 1, 1890.

facility for contagion and the spread of infectious disease. The only factor that can be considered is that of race, with its powerful influence in predisposing to or giving immunity from the operation of morbid processes. The influence of race is marked, and I presume will not be doubted by anyone. The negro is known to be less susceptible to malarial fevers and to scarlet fever than is his white brother, but more prone to strumous or scrofulous affections of all kinds. The Hebrew is generally supposed to be particularly liable to glaucoma, while the Irish are peculiarly susceptible to trachoma, and wherever they go they carry this predilection with them, even when the conditions of life are infinitely better than those of their native country.

My first acquaintance with trachoma and its results was in a part of Eastern Tennessee which has an altitude of from eleven hundred to fourteen hundred feet. There, among a force of workmen, chiefly composed of Irishmen and negroes, the Irish laborers would have trachoma, often in its worst form, while the negroes associated with them never had the disease. So that an altitude of seven hundred and fifty feet more than is sufficient to give immunity in Europe did not give security to these Irishmen. Farrovelli and Gazziniga also found that altitude was not the only factor, and that trachoma occurred in what was otherwise a very healthy locality.[2]

All of these observations point, it seems to me, to the fact that there must exist in the form of a dyscrasia a predisposition to the disease, just as tuberculosis almost always requires for its development the existence of what is generally known as a "tuberculous predisposition." Trachoma must be something more than a local disease, and it cannot be a purely contagious affection. In fact, there are some who doubt whether it is contagious at all.[1]

This diathesis, while it bears considerable resemblance in certain of its manifestations to tuberculosis and scrofula, must be quite distinct from them in other very important characteristics, for the negro race is very subject to the ravages of both scrofula and tuberculosis, scrofulous affections of the cornea and conjunctiva forming a large percentage of their ocular diseases.

The influence of this view of the pathology of trachoma upon our therapeutics must, it seems to me, be radical. We should cease to treat merely the local manifestation of the disease and should turn our attention to the diathesis lying back of it. We are not yet sufficiently acquainted with the diathesis to enable us to indicate more than a few points that should be considered in its further study. Among these, climate and particularly altitude seem to be the most important, though it is probable that there are factors other than climate and altitude which will have to be considered. If these views are correct, the placing of trachomatous patients among the best possible hygienic surroundings becomes a matter of necessity.

[1] Professor George C. Kober, of Washington, who has had an extensive experience in Northern California, informs me that he has frequently seen trachoma at an altitude of 4500 feet, particularly among the Indians.

JOINT-INJURIES OF THE UPPER EXTREMITIES.[1]

BY CHARLES D. BENNETT, M.D.,
OF NEWARK, N. J.

JOINT-injuries are always serious, even when the apparent and immediate damage is slight. So much of a person's usefulness is dependent on the free and natural movements of the joints, that any study of articular injuries, or any time spent in considering their treatment, cannot be thought wasted.

The results of treatment are always plainly shown in joint injuries. Vicious union of a fractured bone may usually be hidden by some device of dress, but a stiff joint or an unreduced dislocation is a permanent impairment of power and a disfigurement that cannot be concealed. And as all of our more delicate manipulations are performed by the upper extremities, so will a mistake in diagnosis or carelessness in treatment be here most apparent.

The cases recorded in this paper, gleaned principally from the records of St. Michael's Hospital, illustrate some of these conditions. They are reported, not because they are rare or peculiarly interesting, but because they are actual experiences, and afford some idea of what may occur in the experience of any practitioner.

CASE I.—H. D., forty-five years old, was brought to the hospital, September 10, 1877, by her attending physician, for an opinion. Four months previously she had fallen, twisting her arm under her.

The injury was treated as a sprain until about two weeks previously, when another physician was consulted, who doubted the original diagnosis, and brought her for examination.

Examination revealed a fracture through the condyles of the humerus and backward dislocation of the radius. The joint was firmly ankylosed, and the adhesions could not be broken up. She was sent away with the advice to let the arm alone.

CASE II.—C. B., aged ten years, came to the hospital, August 15, 1877. In the preceding June the patient, while wrestling, fell with his arm back of him, striking the elbow. On rising, he could not move the elbow-joint, and had considerable pain. He was seen by a physician, who did not recognize the injury, and who treated him with

[1] Read before the Newark Medical and Surgical Society, October 16, 1890.

liniments. On admission a backward dislocation of the radius and ulna, with firm adhesions, was diagnosed. Under chloroform an unsuccessful attempt at reduction was made, which caused much swelling and pain. This, however, with the use of evaporating lotions, soon subsided, and the boy was discharged unimproved, with the joint firmly ankylosed at a slight angle.

Case III.—A Sister of Charity, aged about fifty years, slipped, and catching at a beam above her, sustained an injury of her shoulder.

Her arm immediately became helpless, and painful on being moved. A physician, evidently believing the injury to be only a contusion, prescribed rest, evaporating lotions, and, later, rubefacients and blisters, but the immobility continued. Six weeks after the accident another physician saw the case, diagnosed a partial dislocation of the humerus, and attempted reduction. He claimed to have succeeded, although the disability continued.

Six weeks later the patient came to St. Michael's Hospital and an unreduced subclavicular dislocation of the humerus was diagnosed.

At a later consultation doubt was thrown upon this opinion, some of the staff believing that the lesion was a fracture of the anatomical neck of the humerus, and although measuring over the shoulder girdle and under the axilla showed one-half inch more than the other side, and the arm from acromion to olecranon was one-half inch shorter than the uninjured limb, the doubt prevailed, and it was decided that nothing could be done.

Case IV.—A boy, aged thirteen years, sent to St. Michael's Hospital, May 24, 1889. While fighting he fell with his arm under him. On rising the arm was stiff and sore, and a physician who treated him for several days finally sent him to the hospital with a diagnosis of lateral unreduced dislocation of the elbow-joint.

On examination the elbow was found much swollen and presented all the evidences of an abscess on the inner side. The parts were so tender that nothing could be done until ether was given, when the abscess was opened, a large amount of pus let out, and the fact that no dislocation existed clearly established.

The wound healed well and the joint promised to be as useful as before, when the boy's natural disposition asserted itself and he eloped from the hospital. I saw him two months later when the joint-motion was considerably impaired.

Case V.—C. B., aged twenty years, admitted to the hospital, June 19, 1886. On May 29th, she fell down a flight of stairs, striking on her head and on the anterior surface of her shoulder. She was treated by liniments and electricity.

Upon examination great tenderness over the tuberosities of the humerus, atrophy of the deltoid, and induration about the insertion of the deltoid were found. The elbow could not be raised from the side.

The tenderness and pain were relieved by soothing applications, and a few days later, the patient being under ether, a dislocation of the shoulder was reduced, and in a month she was discharged well.

These cases are instances of unfortunate mistakes. Three of the patients are permanently crippled, and their ability to maintain themselves and their families is seriously impaired. The injuries are not peculiar or unusually hard to diagnose, but the doubt that prevailed in Case III. illustrates the necessity of giving every joint-injury, however trivial, a thorough and painstaking investigation.

The two following cases are cited to show that when the proper diagnosis has been made, zeal in interference must be tempered by judgment, or the original injury may be rendered more serious:

Case VI.—C. F. H., aged eight years, fell sideways with outstretched arm against a wall. He was immediately brought to the hospital, where the exact nature of the lesion was not determined. The arm was bandaged and the boy sent home. On the next day the diagnosis of partial inward dislocation of the forearm was made, but for some reason the application of a lotion was the only treatment prescribed, and the boy was directed to return when the swelling had subsided.

Two weeks later he returned, and under ether reduction was attempted, but failed. During the attempt fracture of the lower extremity of the humerus occurred. All efforts at reduction were abandoned, and the arm was extended and placed in splints. In two weeks passive motion was commenced, and ultimately a useful arm was obtained.

Case VII.—T. S., aged thirty-one years, was brought to St. Michael's Hospital February 14, 1883. In the preceding October the patient had an attack of acute rheumatism confined to the left elbow, from which he recovered in about three weeks, with a stiff joint. Eight attempts to break up the adhesions, the patient being thoroughly anæsthetized, had been made, and resulted in acute suppurative arthritis, which opened through six sinuses. Patient was temperate and gave no history of syphilis or struma.

On admission the elbow was greatly swollen and inflamed, and around the joint the bones were enlarged. He had profuse night-sweats and was much emaciated. A poultice was applied to the elbow, quinine and iron were given, and amputation was advised.

The advice was not followed, but the patient's general condition improved, and in six weeks he left the hospital much better, but with a useless arm.

The cases that follow are recorded not merely because they were severe injuries and interesting in themselves, but also because they are fair types of a peculiar class of injuries—buffer accidents. Many similar cases come to St. Michael's Hospital, the injuries varying in degree from a slight bruise to the absolute destruction of a limb, for which amputation is the only treatment.

The crushing force exerted by two loaded cars coming in contact is immense, and in an arm caught between them the resulting cellulitis is always severe,

and if sloughing occurs, it is always extended, and the injury is generally greater than is apparent.

Often, even where no wound or even abrasion can be found, the skin and subcutaneous tissue will, in two or three days, turn black, and a slough reaching from shoulder to wrist will form. Hence, in this class of injuries the prognosis should be very guarded, and the almost inevitable cellulitis watched for, and promptly treated.

Some of the cases reported here were possibly not joint-injuries at all, but as the crush included the joint as well as the adjacent soft tissues, and as it was necessary to treat the joints, the cases are included with the others.

CASE VIII.—P. H., aged twenty-two years, while coupling cars, had his arm caught between the bumpers. On admission to the hospital, October 9, 1889, the extremity from hand to shoulder was much swollen. Around the elbow-joint and the upper half of the forearm was a large, fluctuating swelling, probably a hæmatoma. There were extensive abrasions and large bullæ on the inner side of the forearm just below the elbow.

Radial pulse faintly perceptible. Forearm could not be flexed on account of swelling and pain. Although there was no crepitus, fracture was suspected. Evaporating lotions were applied and the arm was placed in a straight splint. Six days later a small slough formed over the olecranon, which separated and left a healthy ulcer. The hæmatoma steadily diminished and the radial pulse became good. On November 23d an abscess which had formed on the anterior aspect of the forearm was opened. Joint-motion improved rapidly under passive movement, and on December 9th the patient was discharged well.

CASE IX.—T. J. C., aged forty years, admitted to the hospital, May 31, 1889. His arm had been caught between the bumpers while coupling cars, and from wrist to shoulder was swollen to about twice the natural size. No pulse at wrist. The swelling about the elbow, especially on the radial side, was very hard. It was impossible to determine whether a fracture was present. An evaporating lotion was applied to the arm and the hand was wrapped in cotton. A straight splint was used.

During the next four days little change took place except that the cellulitis lessened in intensity while the inner side of the arm from the axilla to near the wrist became black. On the fifth day the radial pulse could be faintly felt, and from this time the condition of the arm steadily improved.

The prominent swelling about the elbow, being mostly effused blood, diminished very slowly, and in consequence of the general cellulitis and the pain following any interference with the arm, passive motion could not be practised as early as usual and the joint became very stiff, but under patient treatment this lessened, and on June 26th the case was discharged with orders to report to the out-patient department.

This case was especially interesting in view of the long absence of the radial pulse. The parts seemed ready to slough and the question of amputation was fully discussed, but the final decision to wait proved to be a wise one. Just what arrested the blood-current in the radial artery could not be determined. The radial pulse never regained its former volume and even after entire recovery could be found with difficulty only. Over the upper part of the shaft of the radius and under the hæmatoma remained a hard mass which felt like callus.

Whether the radial was compressed by the blood-tumor, was pinched between the fractured parts of the radius, or had directly suffered in the original crush, was a point on which opinions differed, but there was little doubt that the artery had been practically obliterated and that the pulse was re-established by some anastomotic branch.

CASE X.—P. F., aged twenty-two years, admitted, March 13, 1889. While performing his duties as brakeman, his right arm and forearm were caught between the bumpers of coal cars, the injury being most severe about the elbow. On examination, the entire limb was found much swollen and very painful. Slight subcutaneous hæmorrhage was apparent near the elbow, and between the elbow and axilla, and a few bullæ were formed on the inner side of the forearm. No fracture was found.

The arm was placed on a straight splint and evaporating lotions were at once applied, but the crush had been so extensive that although the skin was not broken, its vitality was gone, and in a few days a slough formed that extended from the wrist to the axilla and included more than one-half the circumference of the limb.

Over the elbow anteriorly, the sloughing opened the joint and a probe passed directly between the ulna and humerus, detected bone that was rough and denuded of cartilage.

With such extensive and deep sloughing there was high fever, with delirium, and later, great depression. The man became very ill, life was in great danger and amputation through the shoulder-joint was seriously considered. But his general condition was too poor, and from the sloughing tissues healthy flaps could hardly have been obtained, so again the decision was to wait, and again the result was a good one. The cellulitis ceased to extend, the slough separated, leaving healthy granulations, the opening into the elbow-joint closed, and after three months the wound had entirely healed, leaving the arm with only slight motion between complete extension and flexion to a right angle.

CASE XI.—W. S., aged twenty years, a brakeman, admitted January 21, 1886. His elbow had been caught between the bumpers of two freight cars.

On examination, two small wounds were found, one on the inner and one on the outer side of the elbow-joint, both of which communicated with fractured bone. Under ether, the joint was found to be completely disorganized, the condyles of the humerus being separated from each other and from the shaft. The tip of the olecranon was broken off

and many small fragments, including articular surfaces, were detected. The soft parts showed little bruising, both arteries could be felt at the wrist, sensation in the forearm and hand was perfect, but little blood had been lost, and there was little or no shock.

Excision of the injured joint was determined upon, and through a longitudinal incision over the olecranon the ends of the bones were turned out, the humerus was sawn just above the condyles, the ulna through the coronoid process on the same level, and the head of the radius was removed. The incision and wounds were closed with continuous silk sutures, a drainage-tube was inserted, a dressing of absorbent cotton applied, and the arm bandaged to a long anterior splint. There was no hæmorrhage and no ligatures were used. During the entire operation the wound was irrigated with corrosive sublimate solution.

For three days after the operation the patient was comfortable, but his temperature varied between 102° and 103°. On the fourth day the arm became very painful, considerably swollen and reddened, and cellulitis was evident from about three inches below the elbow to the shoulders. There was a very slight discharge. The arm was placed on a posterior splint, all dressings were removed, and the inflamed parts treated with evaporating lotions. Two days later the superficial cellulitis had diminished, but sloughs were forming along the incision and the wounds, and there was a free discharge of pus. The wounds were washed out daily with antiseptic solutions and all sloughs were gradually cleared away, among them a section of the ulnar nerve about five inches long.

The fever ceased, suppuration steadily lessened, and bony union was obtained. The man was eventually discharged well, with his elbow fixed in a slightly-flexed position.

An interesting point in this case was in regard to the sensation and motion along the course of the ulnar nerve. Of course, after the nerve sloughed the little finger was paralyzed, and sensation was lost in this finger and in the outer half of the third finger, but before his discharge the patient had some feeling in both fingers and slight return of muscular power. It seems hardly possible that five inches of nerve tissue could be replaced, especially in so short a time, yet in what other way could the return of sensation and motion be explained?

Case XII.—William S., aged ten years, was admitted to St. Michael's Hospital, October 7, 1887. He had fallen from a tree, a distance of about twenty-five feet, striking the ground with the outstretched palm of the right hand.

He was brought to the hospital several hours later, when a compound backward dislocation of the wrist was found.

The extremity of the radius protruded one inch from the wound, and a longitudinal fracture, beginning at the articular surface and extending two inches up the shaft, held tightly one of the flexor tendons. The styloid process of the ulna was also fractured. The protruding end of the radius had been stripped of periosteum, and the wound, which exposed the entire wrist-joint, was full of blood and dirt.

The boy was etherized, three-fourths of an inch of the radius was sawn off, the tendon was released, the wound thoroughly cleansed with carbolic solution, a drainage-tube inserted and the arm put in Esmarch's interrupted splint, held by a plaster bandage.

The wound did very nicely. Only slight cellulitis followed, but there was considerable discharge, which necessitated dressing the wound every two or three days, this being done without removing the splint. Granulating tissue soon filled the cavity and the wound rapidly closed until only a small sinus remained on the palmar surface, through which dead bone could be felt with a probe. The boy was transferred to the out-patient department on December 6th. At that time the sinus remained as described, the dead bone was apparent but firmly attached, and there was considerable motion of the wrist-joint.

He continued a somewhat irregular attendant at the hospital until May, 1888, and when after an absence of six weeks he again appeared, the fragment of dead bone was loose, and by slightly enlarging the opening, a section of the radius, one inch in length, was lifted out, after which the sinus promptly healed and the boy was discharged well.

This was a very instructive case. The injury was severe, the joint was apparently totally destroyed, and amputation seemed the most rational treatment, especially as at the best only a stiff, deformed, and useless hand seemed possible. But when the boy was last seen he possessed every motion of the wrist-joint, although each was slightly restricted. He had perfect control of the fingers, had no deformity except a slight deflection of the carpus to the ulnar side, and, in brief, had almost as good use of the hand as before the accident.

This whole series of injuries, few though the cases be, and perhaps seemingly unimportant, well illustrate the care, patience, and judgment required in general surgical work. By a hasty diagnosis and brilliant operation the case may be easily disposed of, sometimes, however, with a stiff joint or missing limb which more care or less haste might have saved, and there is no doubt that in such cases the surgeon does better for his patient and for himself who adopts and adheres to the oft-quoted maxin, *festina lente*.

MEDICAL PROGRESS.

The Microorganisms of Intermittent Fever.—The researches of Dr. Camilla Golgi (*Archivio per la Scienze Mediche*) tend to show that not all the intermittent fevers are caused by the same microörganism Dr. Golgi states that he has been able to demonstrate distinct differences

between the hæmatozoon of tertian fever and that of the quartan type. Biologically considered, the tertian parasite completes its development in two days, while that of the quartan variety requires three days, and the amœboid movements of the former are more marked than those of the latter. Morphologically a distinct difference may be observed in the early stages of development; the amœbæ of tertian fever have more delicate protoplasm and a sharper contour than that of the amœbæ of quartan fever, while the pigment-granules and the bacillary forms are larger. Finally, segmentation takes place in a less regular manner in the tertian than in the quartan organism. Clinically, the destruction of the hæmoglobin in the red corpuscles is much more rapid in the tertian than in the quartan.

Prescription for Offensive Breath.—The following deodorant mouth-wash is quoted by the Paris correspondent of the *Medical Press and Circular*, October 1, 1890:

℞.—Bicarbonate of sodium }
Saccharin } of each 1 drachm.
Salicylic acid }
Proof-spirit . . . . 6 ounces.

Add one teaspoonful to a cupful of water, and use as a mouth-wash.

An Analgesic Spray.—Dr. Dobisch, of Zwittau, recommends the following as a spray-solution in superficial neuralgias, especially those of the head:

℞.—Menthol . . . . 1 drachm.
Chloroform . . . . 10 drachms.
Ether . . . . . 15 " —M.

This, it is said, will freeze the skin in about one minute. If, in addition to the local effect, a moderate constitutional anæsthesia is desired, a small quantity of the mixture may be sprayed upon the nose and mouth for a moment, the head being covered by a canopy to confine the vaporized solution during a few inhalations.

Treatment of Eczema.—Lustgarten recommends the following ointment in the treatment of eczema:

℞.—Oleate of cocaine . . ½ to 1 drachm.
Lanolin . . . . 3 drachms.
Olive oil . . . . 5 "

This ointment he thinks is particularly valuable in eczema of the anus and genital organs. Two applications should be made each day and followed by the use of absorbent powders. Hot baths are very useful if prolonged. For pruritus of the anus, suppositories of the oleate of cocaine are often exceedingly useful.

Lotion for Sweats.—

℞.—Tincture of belladonna . . ½ ounce.
Cologne water . . . 4 ounces.—M.

Bathe the affected parts.

Solution for Intertrigo.—

℞.—Bichloride of mercury . . ½ grain.
Distilled water . . . 3 ounces.

Dissolve, and after solution is complete, wet compresses with the liquid and place them upon the affected parts, allowing them to remain there for an hour. This may be done three or four times a day when the intertrigo is very severe, but it should be remembered that there is some danger of the absorption of the drug and the production of ptyalism if this treatment is resorted to too frequently. Where intertrigo is so severe as to become gangrenous or diphtheritic, Wertheimer prefers to employ local antiseptics such as carbolic acid, and he also washes the parts with water, alcohol, or tincture of iodine. In cases where there is simply excoriation, diachylon ointment may be mixed with equal parts of olive oil and applied to the affected parts. The diseased area should always be kept perfectly clean and all exudation should be removed as rapidly as possible.

The Administration of Mercury to Syphilitic Infants.—Infants who are born syphilitic, or who contract the disease shortly after birth, improve so wonderfully in many instances under the use of mercury, that the following note from the *Revue Général de Clinique et de Thérapeutique* concerning this subject is of interest:

When the child is from five to six weeks of age, Eloy recommends that 5 to 20 drops of Van Swieten's liquid shall be given each day in milk. (Van Swieten's liquid consists of a solution made by the addition of 1 part of bichloride of mercury to 100 parts of alcohol and 900 parts of distilled water.) At the same time that this liquid is given internally, it is advisable to use inunctions of mercurial ointment, or, better still, to employ mercurial ointment diluted by lanolin, equal parts. After this ointment has been used for two or three days, it is best to administer a hot bath. Wiederhofer, of Vienna, considers that red precipitate in the proportion of 1 part to 100 parts of lanolin is even better than ordinary mercurial ointments for inunctions. Baths of corrosive sublimate are particularly valuable, the patient being immersed every third day for a varying length of time, according to the effect of the drug upon the general system. The bath is prepared by adding three grains of corrosive sublimate and fifteen grains of chloride of ammonium to one-half pint of distilled water. This is poured into a wooden or earthenware bath-tub just before the child is immersed in the warm water, which has already been placed there. When the child is older, that is six or seven months of age, the following prescription may be administered with advantage:

℞.—Biniodide of mercury . . 1½ grains.
Iodide of sodium } of each . 1 drachm.
Distilled water }
Syrup of orange . . . 6 ounces.

Of this give ½ a coffee-spoonful to a child of a year, and 5 coffee-spoonfuls to a child of from five to eight years. In other instances calomel and white sugar may be given, ⅛ of a grain of mercury being used for each dose. Sometimes the protiodide of mercury may be given in the same quantity in place of the calomel, and it is particularly useful in combination with the saccharated carbonate of iron in the dose of ½ grain, enough white sugar being added to give the powder proper bulk.

THE LOCAL PARASITICIDE TREATMENT OF CANCER.

THE nature and general appearance of cancer, more than of other tumors, suggest a microörganismal original; and although there have been absolutely no successful attempts at demonstrating such an idea, the question must be considered as still *sub iudice*. The present state of our knowledge by no means admits the probability of such an origin, but the enticing hope of a brilliant discovery is sufficient to maintain the interest of investigators and clinicians in the subject. Many eminent surgeons continue to apply some such substance as solution of chloride of zinc to the exposed tissues after the ablation of a cancerous growth, to destroy a possible specific microörganism.

This idea of the microörganismal origin of cancerous growths is suggested to POUCEL, Surgeon to the Marseilles Hospital (*La Semaine Médical*, September 10, 1890), by several successful results obtained by him from interstitial injections of bichloride of mercury. This writer details seven cases of growths of a cancerous appearance which were treated in this manner. In two cases of undoubted cancer of long standing and in persons of advanced life the treatment was unsuccessful. Of the five successful cases, one, a woman aged fifty-eight years, without syphilitic, tubercular, or cancerous antecedents, or acquired syphilis, presented a large nodular growth of the left breast, with no retraction of the nipple or ganglionic enlargement. Several interstitial injections, the course of treatment extending over several months, caused the entire disappearance of the tumor, and the patient continues in a normal condition. Another case was that of a woman with a tumor of the right breast, which was large, hard, irregular, and ulcerating, and with a retracted nipple, but no glandular enlargement in the axilla. After a number of injections of corrosive sublimate the tumor disappeared, but the patient died several months later in an attack of angina pectoris, and no histological study of the case seems to have been made. The third of the five successful results was obtained in the case of a retired army officer, who was afflicted with a suppurative periganglionic inflammation of the groin. Upon incision there was found an enlarged, hard, solitary gland in the inguinal chain. The patient confessed to having had a hard chancre a number of years previously and was placed upon antisyphilitic medication, but the growth increased in size, became hard and nodular, and had the external appearances of an old inguinal hernia. After twenty-three days of bichloride injections (ten *séances*, injecting three milligrammes every two days), the swelling completely disappeared and has not recurred. A fourth successful case, the son of the last patient, presented several indurated glands in the groin, which in Dr. Poucel's opinion were of the nature of ordinary lymphadenomata and caused by toxæmia. They were of several years' standing, at first indolent and soft, recently hard and increasing rapidly in size in spite of internal medication—chiefly iodide of potassium and quinine. A daily injection of corrosive sublimate solution caused their disappearance within eight days. The last successful case was not under Dr. Poucel's direct observation, and had been variously diagnosed by surgeons as hæmorrhoids, syphilomata, and cancer of the rectum.

Upon these seven cases rests Poucel's evidence as to the parasitic nature of cancerous formations. In two apparently unquestionable cases of cancer death occurred, and from these, of course, no inferences can be drawn. Of the remaining five the diagnosis in three is confessedly weak, and apparently almost surely mistaken. Of the first two, while the local disappearance of the growth was apparently accomplished, in one the death of the patient within a short time from an attack of angina pectoris coupled with the lack of an autopsy permits the

suspicion of the existence of metastatic foci, angina pectoris being no rare sequel to cancerous generalization. Of these seven cases the last one alone seems worthy of entire credence. It is unfortunate that no histological examinations were made in any of these cases.

The general history of the germicidal treatment of cancer is in accord with these results of Dr. Poucel, each successful report being counterbalanced by innumerable failures, and usually by the stigma of doubt. The local use in such cases of what are now known as antiseptic materials dates far back in the history of modern medicine; and in Philadelphia the local employment of corrosive sublimate in these neoplasms was recorded as early as 1793 (Senter, *Transactions of the College of Physicians of Philadelphia*, 1793, vol. i. p. 245). The use of interstitial or parenchymatous injections was first suggested by Broadbent (*Medical Times and Gazette*, 1866, ii. p. 572), acetic acid being employed for the purpose; and since then various reports have appeared extolling the merits of this or that substance as an injection-material. The vast bulk of evidence as to these methods has been decidedly against any special parasitic cause of the disease. Whether the present suggestion leads to definite results, of course further experience must decide, the evidence in hand being of little value in the face of the mass of contradictory testimony.

SOCIETY PROCEEDINGS.

PHILADELPHIA ACADEMY OF SURGERY.

Stated Meeting, November 3, 1890.

The President, D. Hayes Agnew, M.D., in the Chair.

Dr. J. Ewing Mears reported a case of

OCCLUSION OF THE JAWS OF TWENTY-SEVEN YEARS' DURATION IN A WOMAN AGED THIRTY-FOUR YEARS.

He first read a letter from the patient's brother, a physician of Texas. The letter stated that the patient was badly salivated when six or seven years of age, and that there were considerable destruction of tissue and extensive adhesions. A physician divided all the adhesions and opened the mouth, but left the subsequent treatment to a timid nurse, and the result was a failure. When fifteen years of age and when the ankylosis was complete, she was taken to a prominent surgeon in Nashville, who failed to open the jaws. He said that he could not break up the ankylosis without endangering the maxilla at or near the angles. Her health was good but she could not masticate food. She had had a number of asthmatic attacks and several attacks of facial erysipelas which had promptly yielded to treatment.

On coming under Dr. Mears's care the patient gave a fuller history of her case. She said that the surgeon in Nashville had endeavored to open the mouth by continuous traction applied by means of a wire placed around the jaw. This failed and some years later she went to New Orleans to consult Professor Richardson, of the University of Louisiana, who sent her to Dr. Mears.

Notwithstanding the fact that the space between the teeth would just admit the point of a thin knife-blade, she had been doing duty as a teacher, talking through the teeth. She also presented a condition which has been noted in cases of the same nature, that is, non-development of the bones and soft tissues of the face. She was about five feet eight and one-half inches tall, and yet she had the face of a child—what Dr. Mears has designated as a "baby-face." This, both she and her friends had recognized. After the operation, as could be seen from a photograph, this appearance changed and she now has the face of a woman at her time of life.

Previously to operating the buccal space was entirely obliterated. There was simply an opening between the lips through which could be seen the incisor and canine teeth of the upper and lower jaw, but nothing more. The case was at once recognized as one of cicatricial occlusion. She was etherized, an incision was made through the cicatricial tissue on each side, and the mouth forced open. At the same time Dr. Mears removed nineteen teeth. Those of the lower jaw crossed under the tongue, those of the upper jaw projected in various directions, so that in the oral cavity proper there was scarcely room for the tongue. These teeth had irrupted after the jaws became occluded, and not being able to develop in a proper manner, had taken the positions described. The cavities made by the incisions were packed with five-per-cent. iodoform gauze. This dressing was removed in two days and fresh gauze inserted.

After the painful stage following this operation had passed, the second stage of the treatment was begun, and consisted in the passage of ligatures through the cicatricial mass. These ligatures were deposited as deeply as possible on either side by means of a long needle with an eye near the point, the ligatures being brought out on a line with the position of the last molar tooth. The ligatures consisted of heavy silk, carbolized and twisted, and were tied loosely. In conjunction with this, Dr. Mears used an apparatus which he devised some years ago for opening the mouth and for performing operations on the oral cavity. As was expected, some contraction followed the division of the cicatricial tissue. The object in passing the ligatures was to get a track or canal which, after a time, would be lined by mucous membrane and would permit division of the overlying tissues without reformation and reunion, as we treat webbed fingers or toes. In three weeks' time the tissues over the ligatures were divided and the ligatures were reapplied, using two on each side, one above the other. These were allowed to remain in place for three weeks, when the overlying tissues were again divided, and it was found that an opening of one and three-quarters inches had been secured. The use of the instrument was continued for some time after the patient's return to her home. The speaker then exhibited a photograph showing the result a year and a

half after the operation. She reports that the opening is equal to one and a half inches, taken between artificial teeth.

Dr. Mears said that the result in this case was similar to those that he has secured in other cases in which he adopted the plan of treatment by ligatures. He has from time to time tried simple division of the tissues, but invariably the jaws have again closed. The plan of inserting ligatures is of course adapted only to this class of cases, and not to ankylosis or synostosis of the temporomaxillary articulation. All the incisions were made and the ligatures were deposited within the mouth.

The change in the appearance of the face is quite marked. The shape of the face in such cases is due in part to non-use of the muscles of the jaw, and in part to non-development of the bones. The speaker has reported other cases of this kind, one in which he opened the mouth of a gentleman, in whom the closure was of seventeen years' standing, and although he was thirty-two years of age he had never grown any beard. As soon as the man regained the use of the jaw the beard began to grow and the face was soon covered with hair. This can probably be explained by the increased circulation brought about by the use of the muscles.

In discussing this paper Dr. O. H. Allis said that the condition of the teeth to which Dr. Mears had alluded would hardly seem possible to one who had not seen similar cases. The person cannot keep the mouth in a cleanly condition. If a tooth ulcerates or becomes inflamed it is impossible for a dentist to remove it. The amount of suffering which such a patient must go through can hardly be described. He did not know of an operation that is a greater boon to such patients than that described by Dr. Mears. The speaker has performed it but once, and in this case he signally failed by the ordinary means, but with the assistance of Dr. Mears he secured a good separation of the jaws. In this case a portion of the jaw was removed.

In closing, Dr. Mears said that he cordially agreed with what Dr. Allis said. We can scarcely appreciate the condition of a patient with complete occlusion of the jaw. In some of his cases there was considerable danger from the condition. One patient, a boy, crowded a large quantity of pie between his teeth by the aid of a knife and a stick, so that he was in great danger of asphyxia. Patients dread any inflammation of the pharynx because of the impossibility of local treatment. In some of the cases, when emesis occurs, the vomited matter escapes through the nose. In all the cases there is a great deal of courage and a desire to be relieved, especially on the part of the women. In the case which was reported to-night, the patient lived on fluids. In another case the patient had worn away to a great extent the incisor teeth by rubbing pieces of meat on them in order to get the juice. These operations, he said, give as satisfactory results as any operation in surgery.

Dr. L. W. Steinbach then read a paper on

THE ENDOSCOPE.

The speaker said that he wished to direct the attention of the Fellows to the use of this instrument of precision in the examination of the interior of the male urethra.

The ideal method of examining the urinary passages, or any other cavity, is that which makes them accessible to the eye; such a method has been perfected and is available to every one who cares to employ it.

The urethral speculum, or endoscope, in its simplest and best form, is a cylindrical tube, from four to six inches in length, and one-fourth of an inch in diameter, with a funnel-shaped expansion at its ocular extremity. It is made of hard rubber or polished metal, and for convenience of introduction is provided with a closely-fitting conductor, the rounded extremity of which forms an obturator to the visceral end of the tube.

The illumination is obtained by reflecting the rays of the sun, or of a gas- or lamp-light from a large concave head-mirror, bringing them to a focus on a level with the internal orifice of the endoscope.

No special preparation of the patient is requisite; he is seated on a chair with his back toward the source of light, the garments arranged to expose the pubic and scrotal regions only; the physician, sitting on a chair opposite, introduces the previously-oiled instrument in the manner of introducing a sound.

The penis is seized with the thumb and index finger of the left hand behind the glans, the remaining fingers are placed upon the pubes to steady the organ, whilst the right hand carries the endoscope with the thumb pressing upon the conductor to prevent it from slipping out. The instrument is guided along the centre of the urinary canal to a distance of four inches, which is sufficient to inspect any portion anterior to the verumontanum. When we desire to inspect the prostatic portion of the urethra or more posterior structures, an instrument six inches in length is required, and the patient must be placed in the recumbent posture to enable us to guide the endoscope under the pubic arch. It is necessary to have one or more long probes and a pair of slender forceps for the purpose of carrying absorbent cotton, which is used to remove secretions and deposits of the substance which is employed to lubricate the endoscope, and to apply medicines. The forceps are also used to withdraw pieces of cotton which occasionally slip from the probe. When we bear in mind that the mucous membrane of the urethra is arranged in longitudinal folds, and upon transverse section presents a stellate appearance, we at once understand the image which we behold when the conductor is withdrawn and the secretions removed.

The portion of the urethra seen at one time is necessarily small, but by gradually withdrawing the tube every part of the canal can be inspected. It requires practice and instruction to interpret properly the images that present themselves, but the reward is more than ample when we are able to recognize the different inflammatory stages, congestion, granulations, ulcers, cicatrices and polypi, and can apply our remedial agents in a rational manner directly to the portion affected.

The adverse criticism of this method, which in the hands of a few of its zealous advocates has developed into a science, comes mainly from those who have not taken the trouble to master the subject, or who abandoned it because of the complicated, costly, and unsatisfactory appliances which were deemed necessary.

In discussion Dr. John B. Deaver said that Dr. Steinbach had not referred to the Leiter electric-light endoscope, the instrument that the speaker was in the

habit of using. This is a very satisfactory instrument, and with it the mucous membrane of the urethra can be seen with remarkable clearness. In one case, where divulsion had been practised, a teat of mucous membrane was left which was at once apparent to a gentleman who used the instrument for the first time. This case served to illustrate one argument in the speaker's paper opposing divulsion of strictures, read before the American Medical Association. He has been able to cure many cases of gleet in which he was unable to discover a stricture of large calibre with the urethrameter, which he considers the best means for discovering this most common cause of gleet, by making applications to the granulating membrane through the endoscopic tube.

A man was recently brought to him who, four days after suspicious intercourse, had localized pain one inch within the meatus and an induration along the floor of the urethra with slight discharge. In making the urethroscopic examination an ulcer was found which presented the appearance of a chancroid. There was also unilateral enlargement of the glands. The ulcer was touched with a fifteen-grain solution of nitrate of silver, and after three applications it was well. This could, of course, have been accomplished with the tube which Dr. Steinbach referred to.

A urethroscopic tube six inches in length, Dr. Deaver thinks, is not of much service without the incandescent lamp. With the lamp there is no difficulty in exposing the prostatic urethra, although there is some pain caused by the introduction of the instrument beneath the triangular ligament. In a number of cases he has satisfied himself of the presence of pathological conditions of the prostatic urethra, particularly in impotence, of which these lesions are the commonest causes and in which he has obtained satisfactory results from applications through the tube.

He calls the instrument a *urethroscope*, which he thinks is a better name than *endoscope*.

In closing, DR. STEINBACH said that he wished to indicate only one method of making these examinations. He has had ample experience with the instrument which Dr. Deaver mentioned. It is surprising that we do not use these instruments more extensively in the examination of the urethra, the deep urethra, and the bladder. In the University of Vienna there has been for the past ten years or more a chair, occupied by Dr. Grünfeld, devoted to this subject. They have daily clinics, and examine from twenty to one hundred patients. The professor in charge, while showing all the various instruments devised for this purpose, teaches his pupils to use the simpler forms and those which are cheap. When we wish to examine the bladder or some particular growth in the urethra, the electric light is probably better, but in ordinary cases the light reflected from the head-mirror answers every purpose. A four-inch tube is sufficient for most purposes. The longer tube is necessary for the deeper urethra and its introduction requires more skill. When we wish to examine the bladder it is necessary to have a glass obturator, to prevent the escape of urine through the tube.

Dr. Steinbach then showed one of the most recent forms of the electric-light cystoscopes and some of the simpler forms of urethroscopes, which he described.

TRI-STATE MEDICAL ASSOCIATION.

Second Annual Meeting,
held in Chattanooga, Tenn., October 14, 15, and 16, 1890.

Continued from page 520

SECOND DAY.—EVENING SESSION.

The Association met in Stone Church, and was called to order at 7.30 P.M. An

ADDRESS OF WELCOME

was delivered by DR. G. W. DRAKE, and was responded to by Dr. G. C. Savage, of Nashville.

This was followed by the President's Address, entitled

"THE DOCTOR."

The President said that the man who starts out to be a doctor must understand that the life is one of toil. The laggard, the indolent, the careless, or the sluggard never succeed. The doctor must be educated, not as that term seems to be understood in these days. Modern education, he feared, is too much a process of *stuffing* and *cramming*. The term education means more than this. To educate is to draw out, to enlarge, to expand, to develop, and to strengthen.

THIRD DAY.—MORNING SESSION.

DR. T. HILLIARD WOOD, of Nashville, Tennessee, contributed a paper on

HYPERTROPHY OF THE TONSILS.

He said that the treatment of hypertrophy of the tonsils has been subject to many variations. If the enlargement be due to swelling of the mucous membrane or to engorgement and congestion of the tonsil, the application of astringents may be of service. The most useful local remedies are the subsulphate and perchloride of iron (about one part to six or eight parts of water or glycerin) and alum or tannin in powder. But where there is true overgrowth, the remedy must be of a destructive character, and escharotics, not astringents, must be used. For this purpose "London paste" is useful, and should be applied once or twice a week. This will produce a slough, and repeated applications will reduce the gland to the normal size.

Constitutional measures to effect reduction of the tonsils include remedies to combat the diathesis upon which the enlargement often depends, such as iodide of potassium, and cod-liver oil; the general tonics, such as the preparations of iron, and the simple bitters, are also useful.

With reference to operative treatment, excision by the tonsillotome is most popular, although the speaker prefers the bistoury and vulsella forceps. The operation is rendered painless by applying to the tonsil a solution of cocaine, and by injecting, with a hypodermic syringe, a few drops of the solution into the substance of the gland. As a rule, general anæsthetics should not be used.

To reduce to a minimum the danger from hæmorrhage, we have the comparatively bloodless operations by the cold snare, ignipuncture, and the galvano-cautery amygdalotome. Of these the galvano-cautery amygdalotome seems preferable, and is highly recommended by Wright, of Brooklyn. Ignipuncture is tedious, requiring repeated applications, and is attended by consid-

erable pain. Moreover, it cannot be employed in the cases of refractory children.

In discussing this paper Dr. N. C. Steele, of Chattanooga, said that the amount of hæmorrhage during tonsillotomy depends upon the condition of the tonsil. He uses the bistoury in adults and the tonsillotome in children.

Dr. E. T. Camp said that he had been able to reduce hypertrophied tonsils without operation, by using iodized phenol locally, and general remedies.

Dr. George A. Baxter suggested painting the tonsil with flexible collodion.

Dr. Savage said that there were two indications for operating, viz.: Repeated attacks of tonsillitis and interference with breathing. He uses Mathews's tonsillotome and never applies cocaine. From personal experience he knows that the operation is not painful.

Dr. Gahagan suggested cold food and drinks in cases of incipient tonsillitis.

Dr. Reeves thought that in removing the tonsils we leave cicatricial tissue which alters the quality of the voice. He uses tincture of iodine locally.

Dr. Willis F. Westmoreland, of Atlanta, Ga., said that the enlargement of the tonsils is due to exposure, hence the greater number of cases in males. He prefers the bistoury, and has abandoned cocaine because it increases bleeding. Ignipunctnre is too painful.

Dr. Frank Trester Smith, of Chattanooga, resorts to ignipuncture when he cannot get consent to excision. Bleeding may continue for a long time after the use of cocaine. The indications for operation are (1) difficult breathing, (2) unnatural voice, and (3) recurring tonsillitis. The voice after operation improves, as a rule.

Afternoon Session.

Dr. E. A. Cobleigh, of Chattanooga, read a paper entitled

A CASE OF REMARKABLE INJURY, WITH RECOVERY,

and exhibited the patient.

The patient while working in a well was struck by the sharp end of a heavy drill one inch in diameter, which fell about forty-five feet. The implement penetrated the back of the neck, ploughed through the tissues, and emerged from the right side of the chest, protruding about eight inches. The man stepped down from the platform on which he was working, supported himself against the side of the well, and called on a fellow workman to pull out the drill. A stalwart negro tried to do so with both hands, but failed. He mounted the platform and tried again by a steady pull, which did not budge the impaling instrument. He then resorted to a to-and-fro motion with the powerful leverage of the long handle, and was thus able to loosen and extract the drill from above.

The patient was now very imperfectly fastened to the well rope with a noose passed around him, and was drawn to the surface, placed in a chair and conveyed to an adjoining work-room. The patient is twenty-eight years old, five feet and eleven inches high, and weighs 185 pounds, having a magnificent physique.

Examination showed that the wound of entrance was situated one and one-half inches to the right of the spinous process of the fifth cervical vertebra, and that the drill had barely missed the spinal column. It passed downward and very slightly forward and to the right, leaving a rather smooth, oval opening with somewhat inverted edges, resembling the wound of entrance of a round shot, and not as large as one would expect from the size of the wounding instrument, yet sufficiently large for the cervical muscles and fascia to be plainly seen. The shape of the wound caused it to close like a valve, yet air was entering and escaping with a pink froth at nearly every respiratory effort. There was not much hæmorrhage.

From the neck the drill passed into the chest cavity between the scapula and the clavicle, without damage to either of these bones, impinged on the third and fourth ribs, which were fractured in the line of the wound—the fragments evidently being parted as by a wedge while the drill was *in situ*—then passed down on the anterior and outer surface of the fifth and sixth ribs without injury to either, and emerged by a large gaping and ragged wound, with everted edges, at the inferior border of the sixth rib, its centre being at the time of the examination two inches below and one and a half inches to the right of the nipple. There was only moderate bleeding from this wound, into the opening of which Dr. Cobleigh could introduce the tips of three fingers, and no air was escaping. The skin and subcutaneous tissues seemed to be absolutely deadened by the magnitude of the injury, and to have lost their normal elasticity. He passed two fingers into the wound, entering the pleural cavity under the broken ends of the lower fractured rib, which could be distinctly felt. Everything was torn and indefinite, the ends of the broken bone were removable, but he was not able to satisfy himself whether the subjacent lung surface was injured, though he thought it was. The length of the wound was fourteen and a half inches.

On withdrawing the fingers the wound closed by the collapse of its sides, which prevented profuse external hæmorrhage. There were intense pain and a marked degree of shock as shown mainly by the pulse, the mind remaining clear throughout. The integument, however, was quite clammy, and the patient complained a great deal of chilliness, but had no pronounced rigor. There were extreme rapidity and difficulty of respiration, and Dr. Cobleigh believed that the man would die in a short time, especially as the signs of depression were increasing fast, the pulse becoming flickering, irregular, and intermittent, and the mucous surfaces blanching.

Dr. Cobleigh regards the recovery of the case as remarkable and fit to be recorded with the celebrated "crow-bar" case of Maine, and with the later case of abdominal perforation by a railroad coupling-link which happened a few years ago in Kentucky.

Dr. Willis F. Westmoreland, of Atlanta, Georgia, read a paper on

MORBID REFLEX NEUROSES AMENABLE TO SURGICAL TREATMENT.

Dr. H. Crumley, of Chattanooga, presented a case resembling epilepsy, which was examined by many members of the Association.

Dr. J. R. Rathmell, of Chattanooga, reported a

CASE OF ABSCESS OF THE LIVER.

The patient had dysentery in July, and Dr. Rathmell was called to see him on December 17th. The abscess began to discharge through the lung on December 21st, and continued till February 27, 1890, when the patient died. No autopsy was made.

DR. TOWNES followed with a paper on

DILATED CARDIAC HYPERTROPHY, WITH NEPHRITIC COMPLICATIONS,

illustrating his paper by specimens of the condition and by other specimens for comparison. Attention was called to the etiology, and especially to alcoholism and its effects upon the kidneys and liver. The weight of the heart shown was twenty-six and a half ounces. The kidney was an example of those termed by Formad, of Philadelphia, "pig-back."

In the treatment of this patient tincture of digitalis was administered, at first 10 drops, increasing later to 60 drops every hour. Then tincture of strophanthus was given, 20 drops, three times daily, and the heart-beats were reduced from 124 per minute to 47.

EVENING SESSION.

DR. R. J. TRIPPE, of Chattanooga, reported a

FATAL CASE OF PERITONITIS,

which occurred in a muscular negro, as the result of a blow on the abdomen with a crow-bar.

DR. C. H. HOLLAND, of Chattanooga, reported a case of

PHLEGMONOUS ABSCESS

occurring in a man twenty-five years old.

DR. J. H. ATLEE, of Chattanooga, reported a

CASE OF OVARIOTOMY.

In May, 1889, he was called to see Mrs. L., white, aged twenty-one years; married for two years without issue. Menstruation began at the age of fourteen years, and was regular. Immediately after marriage she noticed an enlargement in the left side of her abdomen, which gradually increased until it became so large as to impede locomotion and interfere with respiration.

Dr. Atlee diagnosed multilocular cyst of the left ovary, and decided to operate. Two weeks later, on the day appointed for the operation, he found her with a pulse of 120, a temperature of 103°, and very rapid respiration, and in the presence of these symptoms he thought it best not to operate. Upon the patient's solicitation Dr. Atlee performed paracentesis and drew off thirty pounds of a thick coffee-colored albuminous fluid, which presented, under the microscope, the ovarian cells of Drysdale. Ten days thereafter he removed by abdominal section a tumor weighing forty-five pounds, which in every way confirmed his diagnosis. Before removing the tumor he secured the pedicle, which was short and thick, with two ligatures, each ligature including one-half of the pedicle.

About the eighth week after the operation symptoms of cystitis, with difficult and painful urination, appeared. The urethra was found to be occluded with a foreign body which, upon removal, was identified as one of the ligatures used in tying the pedicle. About the sixth month after the operation cystitis reappeared, and gradually increased in severity until the second ligature was passed from the bladder. This ligature Dr. Atlee now has in his possession. The patient has since remained in perfect health, and is now a strong, healthy woman.

DR. FRANK TRESTER SMITH followed with a paper entitled

FLUORESCEIN IN THE DIAGNOSIS OF EYE-DISEASES.

DR. J. E. PURDON, of Cullman, Alabama, contributed a very elaborate paper on the

DYNAMICS OF MEDIUMISM,

and arrived at fifteen conclusions after a long and careful study of the subject.

DR. W. C. MAPLES, of Bellefonte, Alabama, read a paper on

SOME IRREGULAR FORMS OF EPILEPSY, WITH REPORT OF A CASE.

Dr. Maples thinks that the case reported was one of epilepsy, although in some respects it resembled hystero-epilepsy. His reasons for thinking it to be a case of epilepsy are:

1. The amount of fever. In hystero-epilepsy there is generally but little or no fever. Some authors assert that we may have a true hysterical fever, but the weight of authority is against that opinion.

2. The complete unconsciousness.

3. The biting of the tongue. Hystero-epileptics seldom or never injure themselves.

4. The facial expression and pupillary phenomena. The facial expression is generally calm and serene throughout a hystero-epileptic attack.

5. The absence of hysterical phenomena in the interval between the attacks.

6. The sex. Hystero-epilepsy rarely occurs in males.

DR. J. D. GIBSON, of Birmingham, Alabama, presented a paper on

URETHRAL STRICTURE AND ITS COMPLICATIONS.

He considers the acorn-pointed sound the most convenient and practical instrument for the detection of stricture.

Dr. Gibson said that if he were compelled to use only one instrument in the treatment of strictures, that instrument would be the sound. He believes that if it is properly used, there are very few strictures that cannot be relieved, and that the only cases in which a urethrotome is necessary are tight and unyielding strictures in the pendant urethra or at the meatus. Inexperienced men are apt to be disappointed in the use of the sound, simply because they try to go too fast; the idea should be to dilate the stricture and produce absorption, not rupture.

Internal urethrotomy, while often abused, is a potent means of treating urethral stricture, it being especially applicable to old and firm strictures in the pendulous urethra and meatus.

DR. P. S. HAYES, of Chicago, followed with a paper entitled

NOTES ON APOSTOLI'S METHOD IN THE TREATMENT OF UTERINE FIBROIDS.

He said that one of the most clearly demonstrated

facts of the Apostoli method is that by means of it all uterine hæmorrhages, not puerperal, can be arrested.

All observers recognize that the positive pole is the one to be connected with the intra-uterine electrode. The reason for this is, that in electrolysis, especially when the electrolyte—the fluid undergoing electrolysis—is blood, the clot formed around the positive pole is small and dense, while that around the negative pole is large and flabby. Knowing, as we do, that oxygen, chlorine, and the acids are liberated at the positive pole when electrolysis is performed on the tissues of the body, and also knowing that hydrogen and the alkalies are liberated at the negative pole, we have only to apply our knowledge of the action of the acids and alkalies on the blood to explain the observed phenomena.

The occurrence of uterine hæmorrhage does not contraindicate the use of the method.

One of Dr. Hayes's patients, suffering from menorrhagia, came to his office, stating that she was drenched with the discharge, the hæmorrhage having occurred when she was some distance from her home. Dr. Hayes used the intra-uterine electrode connected with the positive pole, and passed a current of from 60 to 80 milliampères for eight minutes. The patient went home, a distance of three miles, and was in bed the remainder of the day. On the next day she was about the house, and the flow had nearly ceased. This period was by far the least severe that she had had for several months, and the amount of time spent in bed was three-fourths less.

Officers for 1891.

President.—Dr. Robert Battey, Rome, Ga.

First Vice-President.—Dr. E. T. Camp, Gadsden, Ala.

Second Vice-President.—Dr. Richard Douglas, Nashville, Tenn.

Third Vice-President.—Dr. D. H. Howell, Atlanta, Ga.

Secretary.—Dr. Frank Trester Smith, Chattanooga, Tenn.

Treasurer.—Dr. S. B. Wert, Chattanooga, Tenn.

On motion, the Association adjourned to meet in Chattanooga, Tenn.

THE NEW YORK SOCIETY OF MEDICAL JURISPRUDENCE.

Stated Meeting, November 10, 1890.

The President, Landon Carter Gray, M D., in the Chair.

Dr. E. C. Spitzka read

A REPORT ON THE EXECUTION OF WILLIAM KEMMLER.

After alluding to the fact that the New York Society of Medical Jurisprudence had taken the first steps to bring about a reform in the methods of capital punishment, which had led rather prematurely to the passage of the law establishing electrothanasia as a substitute for hanging, Dr. Spitzka said that the chief objection to this new mode of execution is the complicated machinery necessary. He then vividly described the execution of Kemmler, already too familiar to the general public in many of its details, in order to show the favorable, as well as the unfavorable factors which entered into this particular case. He has witnessed a number of hangings, but never before was he unable to recognize at once the condemned one, by his appearance or demeanor. Kemmler's manner was so calm and yielding that it was indeed necessary for the warden to introduce him to the assembled witnesses.

After quoting Kemmler's last words, which he said had been correctly reported only by Dr. Carlos Macdonald, he described how the doomed man assisted in the preliminary arrangements, including the application of the electrodes. When the awful moment came, his body was thrown into a tetanic spasm, and, in the speaker's opinion, death occurred in an infinitesimal part of a second. The spasm lasted for the seventeen seconds during which the current was applied, and involved every muscular fibril, so that there was not only rigidity, but also quivering. The violence was so great that it would be easy to believe, that were it not for the secure manner in which the man was fastened to the chair, the tremendous force of the muscular contractions would have caused many fractures.

During the first application of the current, a peculiar pallor appeared on the man's scalp and spread down to the head-band, and the intense purplish congestion of the capillaries which surround the naso-labial fold showed distinct post-mortem hypostatic congestion, bounded by a serrated line. When this congestion appeared Dr. Spitzka announced that the man was dead. Up to this time, of course, no one had dared to feel the pulse, or make an examination of the body by touch. It was evident that the other witnesses also considered the man dead, for they gathered around the table, and prepared to sign the legal document as required by law.

At this time the victim's pulse was absent, the pupils were insensible to light, and one cornea was flaccid. The marks of his suspenders, and of every fold in his clothing, were traced upon his body in a singular manner. During the muscular spasm the thumb of one hand was driven into the finger, and when blood oozed from this wound one of the witnesses exclaimed that life was returning. This immediately produced a panic among the spectators, and Dr. Spitzka, as he himself says, made the great mistake of ordering the current turned on a second time. Again the body was convulsed, but the contractions were more like those seen in a galvanized frog when the contractility is becoming exhausted. At the time Kemmler met his death it was probable that he was in a state of "expectant inspiration;" hence the bubbling of air through the thick mucus which had collected in the mouth.

In cases of death by powerful electrical currents, or by lightning, the fluidity of the blood has been commented on, and it is well known that under such circumstances bleeding from an incised wound is no proof that life is not extinct. Dr. Spitzka thought that such a phenomenon could be reproduced even as late as the fourth or fifth day after death. His examination made after the final cessation of the current, showed the absence of the tendon and pupillary reflexes, and the hypostatic congestions already noted. Seven or eight seconds after the cessation of the current there were repeated explosions of intestinal flatus, followed in a few seconds by a profuse flow of urine. After the first application of the cur-

rent there was an erection of the penis and an emission of semen. The erection seemed to be produced by the erector muscles rather than by the turgidity of the blood-vessels.

Dr. Spitzka said that his object in bringing this subject before the Society was to direct particular attention to the uncertainty of all the usually-accepted signs of death. In the examination just mentioned he found that on touching the convict's ear it became pale, but on relinquishing his grasp the color immediately returned. This phenomenon has been made the subject of a successful prize essay, in which it was stated that the absence of the sign is positive proof of death. Yet after this man's body had been completely dissected, and the lungs, heart, intestines, brain, and spinal cord entirely removed, the phenomenon was repeatedly observed. He has observed the same thing in a few other cases in which he made an examination very soon after death. In the present instance the fluidity of the blood might partially explain the persistence of this phenomenon.

In speaking of the arrangements of the apparatus at the Auburn prison the author criticised quite severely the placing of the switches, and especially of the volt-meter in a room separate from the execution-chamber, thus making it impossible for the official physicians to observe the voltage of the current. On this occasion the volt-meter did not work properly, and he believed it was not intended that it should do so; for at trials both before and after the execution, it failed to work well for more than a few moments. The only way the physicians could judge of the condition of the current was by the appearance of the incandescent lights.

As is well known, much opposition has been raised against the execution by electricity on account of the State's selection of the dynamo of a particular corporation. It is worthy of note that the first accidental death by powerful electric current, occurred in Buffalo three or four years ago with a current from a Brush machine; and it would have seemed natural for the State to select the machine which had first so unfortunately demonstrated its ability to kill. The State should have but one plant, centrally located, and provided with a dynamo especially constructed for the purpose, and capable of generating a current of about 3000 volts. This machinery should be under the charge of a thoroughly competent electrical expert. The neurologist or ordinary medical man knows very little about these powerful currents, and should only direct the selection and proper application of the electrodes. Dr. Spitzka said that a collar electrode could be so constructed that it would hold the victim firmly without strangling him, and while securing better contact and easier application than the head electrode, would avoid the only preliminary to which Kemmler objected—the shaving of the scalp. The spinal electrode is even worse than the head electrode. It is unnecessary to test the resistance of the convict's body before the execution. All that is required is to employ the highest obtainable voltage and to apply it for a brief period. This would lessen the probability of burning, avoid the revolting spectacle of convulsions long after life is extinct, and would convince the public that death was instantaneous. The great cost of this method of capital punishment will probably prevent its introduction into other States.

Notwithstanding the disadvantages mentioned, Dr. Spitzka said that the execution of Kemmler was a more decent and dignified vindication of the law than the cases of hanging that he had witnessed.

In view of the part taken by the Society of Medical Jurisprudence in this matter of reform in the execution of the death penalty, Dr. Spitzka thought it might justly claim to be in the advance guard of forensic medical progress.

In discussion, DR. CARLOS MACDONALD, who prepared the official report at the request of the Governor, said that he had but little to add to Dr. Spitzka's report. In criticising the medical witnesses of this execution, it should be remembered that their advice was sought in regard to only one matter—the duration of the application of the current; and that even about so important a matter as the application of the electrodes, they were not consulted. At the preliminary tests made some months previously to the execution, it was decided to use a helmet electrode, and also a form of chair which had been recommended by Dr. Macdonald; but for some unknown reason both of these decisions were changed. He considered the discarding of the helmet electrode a mistake, as experiments on animals have shown that the most effectual mode of application was through an electrode embracing the frontal region. The great error had been in not continuing the current a little longer, remembering that the probable voltage was not nearly so great as had been intended. It probably did not exceed 700 volts; while, judging from experiments on animals, it should have been 1000. He believed that with proper contact, such a current, if applied for from fifteen to twenty seconds, would invariably cause instant death. He went into the switch-room in the Auburn prison in the interval between the applications of the current, not knowing that it was against orders, and found the incandescent lamps burning dimly. He recognized Mr. Davis in the room, and asked him, "What is the matter with your current?" to which Mr. Davis replied, "There is something wrong down at the dynamo." He had no time to make further inquiries, for he was sent out of the room. He believed that if contact had been maintained five seconds longer in the case of Kemmler, no muscular movements would have been observed.

DR. SACHS spoke of the execution as a "scientific experiment," for the resistance of the body varies so enormously in different subjects, and in the same subject at different times, that there is necessarily the greatest uncertainty as to the results. The Commission appointed to investigate these points, did not consider the differences between the lower animals and human beings, and consequently their conclusions were mere guesswork. He was, therefore, surprised that the execution proved so successful.

The President, DR. GRAY, also spoke of resistance, and endorsed the views of the preceding speaker. He thought that in addition to these elements of uncertainty, there was another obstacle—*i.e.*, the difficulty which would be encountered if the condemned man should struggle or resist.

The HON. WILLIAM BARNES thought that struggling would finally lead to the abandonment of electrothanasia for a method with fewer uncertainties, such, for instance, as the guillotine.

Dr. N. S. Brill, whose paper originally led to the reform in executions, said that there was less danger of bungling with electrothanasia, when carried out according to the suggestions already laid down, than there was in hanging; and the former had the additional advantage that the execution was constantly under the control of the executioner to the time of the victim's death, while in hanging, the executioner, after springing the drop, has no control whatever.

CORRESPONDENCE.

"RHUS POISONING."

To the Editor of The Medical News,

Sir: Under the head of "Hospital Notes" in your issue of October 25, 1890, I notice a method of treatment advised for "Rhus Poisoning." I have had a very large experience with this form of dermatitis and have never seen the application of "iotio nigra" fail in any stage of the disease. This was suggested to me by Harold Williams, M.D., of Boston. The part or parts may be freely bathed with black wash or wrapped in absorbent wool or cotton previously soaked in the solution. Immediate relief of subjective symptoms follows and the objective signs rapidly disappear. I have never seen untoward symptoms. The only objection to the treatment is, that *the physician makes but one visit.*

NEWS ITEMS.

The Hot-air Clinique of Paris.—A clinique was recently opened in the *Rue de la Chaussée d'Antin*, Paris, for the hot-air treatment of consumptives. Here men, women, and children who have phthisis or are predisposed to it may be treated free of charge. Ranged around the walls of the establishment are a number of small tables, on each of which stands an apparatus for heating the air by means of a large spirit-lamp. From each of the reservoirs issues a rubber tube terminating in a mouthpiece, through which the patients inhale the heated air. The mouthpiece is double-valved, so that the expired air passes out without mingling with that delivered by the apparatus.

The Study of Medicine in Thibet.—The Buddhist Lamas' University, in the Transbaikal Province of Thibet, has a medical course of ten years. According to *Nature*, a traveller named Ptitsyn has returned from that country with a collection of medical books and drugs illustrative of the knowledge and the methods of practice in Thibet. Mr. Ptitsyn remarks that he has found over one hundred diseases described in the Buddhist literature, and of these a mythical origin is ascribed to only two. Strictly medical subjects are not studied until the fifth year of the course, the first four years being devoted to the study of the languages and theology. The eighth year is devoted to astrology, and philosophy is studied in the last two years.

Liabilities of Patients.—Mr. A. M. Hurlock, an attorney of Baltimore, is engaged in an attempt to get a bill through the Legislature of Maryland, which shall render a married woman's estate liable for medical services rendered to herself or to her children. Every now and then rich or well-to-do women with worthless husbands obtain under the present law the medical services of the doctor without compensation, and we think that a law such as proposed will materially help in stopping one of the leaks which wastes the stream of nutrition running into the lean professional purse. We trust that he may be successful, and that his example may prove contagious The principal section of the proposed bill is as follows:

Section 1. *Be it enacted by the General Assembly of Maryland*, That married women shall be jointly liable with their husbands for medical services rendered to such married women or their children, that they may be sued jointly with their husbands for such services, and that judgments obtained in such suits may be a lien on their separate property.

American Academy of Medicine.—The Constitution was altered at the last annual meeting so as to admit, in addition to those possessing the degrees of A. B. and A. M., those who can present evidences of preparatory liberal education equivalent to the same.

Dr. J. E. Emerson, Detroit, Michigan, Chairman of Committee on Eligible Fellows, will forward to any applicant copies of the amended Constitution and By-Laws, List of Members, and other information as to the Academy.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM NOVEMBER 11 TO NOVEMBER 17, 1890.

By direction of the Acting Secretary of War, leave of absence for three months is granted Charles M. Gandy, *Captain and Assistant Surgeon*, Fort Clark, Texas.—Par. 10, *S. O. 206, Headquarters of the Army, A. G. O.*, November 15, 1890.

Walker, Freeman V, *First Lieutenant and Assistant Surgeon* (Fort D. A. Russell, Wyoming).—Is granted leave of absence for one month, to take effect on or about the 15th instant.—Par. 3, *S. O. 85, Department of the Platte*, November 11, 1890.

By direction of the Secretary of War, the leave of absence granted Stevens G. Cowdrey, *Major and Surgeon*, in Special Orders No. 112, Department of Arizona, October 24, 1890, is extended fifteen days.—*S. O. 163, Headquarters of the Army, A. G. O., Washington*, November 10, 1890.

By direction of the Secretary of War, the extension of leave of absence on account of sickness, granted Henry McElderry, *Major and Surgeon*, in Special Orders No. 214, September 12, 1890, from this office, is further extended two months, on surgeon's certificate of disability.—Par. 28, *S. O. 263, A. G. O.*, November 10, 1890.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING NOVEMBER 15, 1890.

Owens, Thomas, *Surgeon.*—Ordered to the Museum of Hygiene at Washington, D. C.

Martin, H. M., *Surgeon.*—Detached from the Receiving-ship "Wabash," and ordered before Retiring Board.

Rixey, P. M., *Surgeon.*—Continued in charge of Naval Dispensary at Washington, D. C., until November 20, 1890.

Green, E. H., *Passed Assistant Surgeon.*—Promoted to Surgeon, November 10, 1890.

Smith, Howard, *Surgeon.*—Placed on the Retired List, November 10, 1890.

ORIGINAL LECTURES.

CRANIECTOMY FOR MICROCEPHALUS—THE LATER HISTORY OF A CASE OF EXCISION OF THE HAND-CENTRE FOR EPILEPSY.

A Clinical Lecture delivered at the Jefferson Medical College Hospital, November 19, 1890.

BY W. W. KEEN, M.D.,

PROFESSOR OF THE PRINCIPLES OF SURGERY.

GENTLEMEN: The first case that I shall show you today is that of the little boy upon whom I operated before you last December. At that time I removed the hand-centre from the cerebrum for the relief of epilepsy.[1] First, as a caution to you, I will tell you of a slight accident that occurred.

You will notice that the scar, instead of being pale as it should be, is somewhat red at one point. Shortly after the operation the boy disturbed the dressings, and I feared that the wound would become infected. A small abscess formed which was followed later by the extrusion of two of the small pieces of bone, which you will remember I replaced. The large 1½-inch button is in good condition. At the second dressing after the operation I wished to remove the strand of horsehairs which had been placed in the wound for drainage, but on taking away the gauze I did not find them. The dressings were then carefully examined, as I thought that the hairs might have been pulled out when the gauze was removed. I then searched for them upon the floor and then carefully and gently in the wound itself, but not finding them I came to the conclusion that the child had pulled the hairs out at the time that the dressings were disturbed and that they had been lost. The wound healed nicely, except at the place where the two fragments of bone came out, which united slowly.

All went well till last June, when the cicatrix became red and irritated and a little later a small sinus formed, in which the horsehairs were found and removed. They were probably cut too short, and when the child disturbed the dressings were pushed into the wound, remaining there from December until June without giving rise to any trouble. I have never before had such an occurrence, and I give you this history so that you may avoid the same accident. I once performed an operation upon a young woman who had been previously operated upon, and found in the seat of the old wound one of the horsehairs which had remained there a year without giving rise to any irritation.

In the present case, in spite of the horsehair, which must have caused some irritation, the boy's condition is much better, although he is not completely cured. The fits have been, as a rule, far less severe and less frequent than before the operation and his disposition is very greatly improved. In fact, he is quite a different boy and more amenable to control, so that he can now play with other children. He is interested in matters of every-day life almost as much as one would expect in a child of his age. His vocabulary also is now quite large, and he is learning quiet kindergarten plays, which he would not have touched or looked at in his restless impatience a year ago.

How far this change in disposition is due to the operation and how far to the careful training of Miss Bancroft and Miss Cox, of Haddonfield, N. J., who have had him in their training-school for feeble-minded children, I am not prepared to say; it is my belief, however, that it is largely due to the operation, as his disposition began to improve while still in the hospital, and especially after he went to his home.

For some weeks after the operation his hand was completely paralyzed, but later it gradually recovered and is now only slightly paretic. The bilateral function of the opposite cortex has reëstablished the function of the lost centre. He can feed himself without difficulty, and you would probably not have noticed the slight defect had I not called your attention to it.

CRANIECTOMY FOR MICROCEPHALUS.

The operation that I next propose to do is the first one of its kind which, so far as I know, has been performed in this country. It has been done only twice in Europe, both times by Lannelongue, of Paris. Lannelongue's first case was that of a microcephalic idiot, the history of which I will read to you.[1]

The patient was a girl, four years of age, born at term and without accident; father aged thirty-eight years and mother thirty-five years, both in good health. No hereditary disease. Five brothers and sisters in good health.

The child's mental development was retarded. She could not take any food but liquids, and up to the age of three years had not walked nor even stood. Within the last few weeks before coming under observation she had babbled a few syllables but no words. Saliva escaped from the mouth constantly. She had the appearance of an imperfectly-developed child of two years. Her eyes were brilliant, but she did not seem to be interested in anything about her, nor could one engage her attention. She was constantly uttering inarticulate cries, and scarcely ever ceased moving. Her height was 77 cm. (30⅜ inches), the circumference of the thorax 45 cm. (17¾ inches). Her legs, while they could not support her weight, were always in active motion. There were no contractures or paralyses; sensibility normal; reflexes not increased; no epileptoid manifestations. Head very much narrowed transversely and

[1] THE MEDICAL NEWS, April 12, 1890.

[1] L'Union Médicale, July 8, 1890.

prominent at the vertex. Nose well developed and aquiline. Forehead retreating and very narrow. Antero-posterior diameter of skull 155 mm. (6⅛ inches), bi-parietal 109 mm. (4¼ inches), bi-frontal 86 mm. (3⅜ inches).

Operation May 9, 1890: A narrow strip of bone was removed on the left side of the sagittal suture, as the left side was smaller than the right. The bone was removed a finger's breadth from the middle line and was 9 cm. (3 9/16 inches) in length and 6 mm. (¼ inch) in breadth. The dura was not opened. The incision in the scalp was made in such a manner as not to correspond with the incision in the bone. The periosteum was not replaced. Healing took place in a few days. During the operation, as well as for four or five days afterward, a serous liquid escaped in small drops from the surface of the dura mater.

Results: On June 15th, that is to say, in five weeks, the child was calmer, the incessant cries had ceased the day after the operation, she took notice of what went on about her, laughed and seemed very happy, comprehended what occurred, tried to talk and pronounced several words. She can now stand alone; she walks with regular steps, tottering a little when she hastens. She no longer drools. Her intelligence seems to have kept pace in its development with the physical improvement. She is now able to eat at the table. She has been under instruction, which may account in part for the improvement.

A second, similar, case, but more pronouncedly idiotic, was operated on June 20, 1890. The incision to the left of the middle line was the same, but another similar portion of bone was removed from the frontal on the left side, leaving a little bridge at the fronto-parietal suture. In other respects the operations were the same. Of course, the time was too short to judge of the result.

The history of the case upon which I am about to operate is as follows:

M. E., aged four years and seven months, was first seen by me on November 3, 1890. Three grandparents are living and in good health. Paternal grandmother had scrofulous glands in her neck. Her mother is aged thirty-three years, father thirty-five years, and both are in good health. She has one sister, nine years old, in good health physically and mentally. The patient's birth was normal and she was a breast-fed baby. At four or five months of age she weighed 25 pounds, at fifteen months 40 pounds, at three years 31 pounds, and at present only 30 pounds. She has never walked, but began to stand at about two years of age. When twenty-one months old she could say "baby," "pretty," "bye-bye," and other words, but since then entirely lost the power of speech. Two years ago she had twenty-four convulsions in one day, probably from teething, which was late; but these are the only convulsions she has had. Had measles and whooping-cough in rather rapid succession when about a year old.

Present condition: She is evidently a healthy but poorly-developed child. Her bones are small, and her head is very small and moderately prognathic, with defective development, most marked in the frontal region, and also in the occipital. Two photographs, one taken at twenty-one months of age, the other a week ago, show the greatest difference in expression, the earlier one being that of a bright, intelligent baby, the later showing a plainly idiotic face. There are no contractures or paralyses. She is constantly moving and wringing her hands, but evidently not from pain. She drools a good deal. The condition of her reflexes is hard to determine because of the constant movements and the want of intelligence. Her mother thinks that she knows her parents and sister. She watches strangers somewhat, but notices little else. Seems to be pleased by having her hat put on, as though she knew it meant that she is going out of doors. All the sutures are firm. The anterior fontanelle, which existed at birth, is entirely closed. Percussion gives a uniform sound all over the skull, and is not painful. She has "drowsy spells" from time to time, often several times a day, when her head falls over and she sinks down almost asleep, but awakens immediately and is as well as ever. These attacks last only two or three seconds. Her intelligence varies considerably; some times she is much brighter than at others.

Measurements: Height, 92.5 cm. (36⅜ inches); circumference of chest, 50 cm. (19⅝ inches); head, antero-posterior diameter, 15.3 cm. (6 1/16 inches), bi-parietal, 11.3 cm. (4½ inches), bi-auricular, 11.6 cm. (4 9/16 inches), bi-frontal, 9.5 c.m. (3¾ inches). Circumference of head, 43 5 cm. (17⅛ inches). The two sides of the head are of equal size. You observe that the head is very small, being about the size of the head of a child eleven or twelve months old.

The result of the examination of the eyes, which was made by my friend Dr. Hansell, is as follows: "The examination was difficult and prolonged on account of the constant movement of the hands and arms, and lack of intelligence preventing coöperation. The pupils responded to light and association, the pupil of one responding in contraction and dilatation to the alternate exposure to light and darkness. Media clear; fundus normal; nerves (optic disks) of good color. The internal squint, said to be present at times, was to-day absent. The patient seemed to have good vision."

The inherent cause of microcephalus we do not know. Formerly it was supposed to be due to premature ossification of the cranial sutures, but the examination of several such skulls has shown that while this may sometimes be the case, yet in the cases examined there was no abnormality in the bony development of the cranium. On the other hand, we know that the growth of the skull keeps pace with the growth of the brain within it; and if the growing power of the brain be weak, a slight resistance on the part of its osseous envelope may be sufficient to check and stunt it. Reasoning in this way, Lannelongue concluded that it was a rational procedure to attempt to remove at least a part of the force that was preventing this enfeebled brain from attaining a larger and more natural growth; and his operation was planned to effect this end. It is too early yet to pass judgment upon the operation as a remedial measure, for so far we have only the report of his two cases. It seems to me an experiment well worth trial. The operation itself, if it does not produce the hoped-for result, is at least little, if any, more dangerous than trephining; and, inasmuch as the dura is not opened, the real danger of the operation should be very small. Of course, the operation is only applicable to children.

I propose to do the operation with slight modifications.

Lannelongue's incision in the scalp was made parallel to the line of the sagittal suture, commencing in front of the lambdoid and extending forward to the coronal suture, then turning off at an obtuse angle downward on the forehead, with a bridge of bone at the coronal suture.

Instead of continuing my incision forward on the forehead as Lannelongue did, I shall there make a curved incision with the convexity backward and all in the hairy scalp. I shall then raise this flap of skin and under it cut out the bone, thus avoiding any scar on the forehead. The incision in the skin will not be in the same line as that in the bone, so that the wound in the cranium will be covered by the scalp. I shall leave no bridge of bone at the coronal suture. The object of the operation is to make the side of the head, as it were, into a bony flap, with an attached base below and a free border above. This flap can be readily expanded even by feeble force from within, and will allow the brain "elbow-room," so to speak, for development. I shall extend it into the frontal and occipital regions, so that these lobes, and especially the frontal, which is probably the seat of the intellectual faculties, may be able to enlarge. As the skull grows stronger and stiffer it will still have strength enough to prevent danger to life from ordinary blows or other traumatisms. It is a matter of indifference in this case upon which side the incision is made, as the cerebral development is symmetrical. A cast of her head has been taken, and at different periods of the child's growth other casts will be taken and the progress of the growth of the head may thus be determined. As the usual mode of making a cast by plaster cream alone is rather objectionable, and in the case of this child, indeed, impossible, I devised the following plan: The head was shaved and rubbed with a little sweet oil. A thin coat of plaster-of-Paris cream was then evenly applied to get a smooth surface. Upon this three or four layers of a common plaster-of-Paris bandage were put on as a "recurrent" bandage, followed by a thin layer of plaster-of-Paris cream, and so on ultimately until the mould was completed. If either the occiput or the frontal portion of the head is so prominent as to prevent the removal of the mould, it may be cut over these places before it dries, the edges of the cut being carefully restored to their original position immediately after removal. No cutting was needed in this case.

In my operations upon the brain I use sterilized gauzes instead of sponges. This gauze is steamed for three-quarters of an hour in a Sattegast steam sterilizer, without chemicals, as I prefer not to use corrosive sublimate in these cases. All the instruments are boiled in a Schimmelbusch sterilizer, and the water in the apparatus is kept boiling during the operation so that any instrument may be quickly sterilized if necessary. One per cent. of carbonate of sodium is added to the water to prevent rusting the instruments.

I have explained the operation to the father and mother of the child, telling them that it is only an experiment, but that I consider that there is little danger in it, and a possibility of doing her great good. Upon these grounds they at once consented to the operation.

Upon making my scalp incision I find that there is unusually little bleeding. I have at former times in operating upon the scalp placed an Esmarch narrow band around the head to prevent bleeding, but this is unnecessary. It adds to the length of what is always a long operation, and I find the hæmorrhage is easily controlled by hæmostatic forceps. The flap is pulled to one side, and I now carefully remove with a half-inch trephine a button of bone from a point about a finger's breadth to the right side of the sagittal suture, so that there is no danger of entering the superior longitudinal sinus. The dura is very carefully separated from the bone, and in this case I think is more adherent than usual. The instrument that I shall use in removing the bone is a pair of rongeur forceps, much more curved than ordinarily, and only one-fourth of an inch wide. In case of hæmorrhage from a branch of the middle meningeal I would quickly bite away the bone over the bleeding part with a forceps and pass a ligature under the vessel by means of a curved needle. The middle meningeal always requires to be ligated in this way. It runs in a tightly-stretched membrane and does not contract and retract like other arteries and thus easily and spontaneously cease bleeding. As the patient should have all the chances for recovery that are possible, I shall operate upon only one side to-day, thus reducing the danger of shock. She will be constantly under my observation; if her mental condition does not improve as much as I desire I shall operate later on the other side. The line of incision in the bone is now complete and extends to within three-fourths of an inch of the supraorbital ridge and backward nearly to the occipital bone, measuring six and one-fourth inches in length and one-fourth of an inch in width.

One rather large branch of the middle meningeal artery is seen crossing the cleft. The forceps are all removed and the flap is carefully inspected to see if there are any bleeding vessels. The hæmorrhage is usually stopped by the forceps, but in case I find any bleeding points I will pass a stitch under them, as I wish all bleeding to be completely arrested before the wound is closed. The periosteum is next cut away from the edges of the groove so that it will not cover it and cause union of the bone. A few strands of horsehair are placed in the groove and are cut sufficiently long to prevent danger of their slipping under the scalp in this case. These hairs will all be removed, except two or three, at the end of two or three days. In sewing up the flap I am careful to get absolute coaptation, so that there shall be no overlapping, as this would expose a surface which must heal by cicatrization. The wound is carefully dressed with sterilized gauze and she will be laid upon her right side to favor drainage. Now, gentlemen, the operation is completed, and we have only to await the future. Her mental traits have been closely observed, so that it may be readily seen whether there is any change in her intelligence.

[Note.—She was entirely well and all the sutures were out in five days. The operation took an hour and convinced me that it could be done in probably one-half that time by a proper pair of rongeur forceps. These I have had made, and I will report upon their usefulness in the future.—W. W. K.]

Deaths from Wild Beasts and Snakes in India.—According to the *Medical Press*, 1587 persons were killed by snakes and 385 by wild beasts in the Madras Presidency, India, in 1889. The number of cattle destroyed was 15,550.

WHAT I HAVE LEARNED TO UNLEARN IN GYNECOLOGY.

By WILLIAM GOODELL, M.D.,
PROFESSOR OF GYNECOLOGY IN THE UNIVERSITY OF PENNSYLVANIA.

Every earnest worker in any field of the inexact sciences finds himself compelled to unlearn as well as to learn. The errors which he discovers and weeds out will usually be traditional teachings—the legacies of our forefathers—for we get many of our opinions, as well as many of our diseases, by heredity. What I have thus learned to unlearn in the treatment of woman's diseases will be the burden of this paper.

To begin, then, I have learned to unlearn the grandmotherly belief that the climacteric is in itself an entity, and that, as such, it is responsible for most of the ills of matronhood, and especially for that of menorrhagia. True, it must be conceded, that as an entity it does seem to disturb the vasomotor system, and through it to cause many severe perturbations, such as tinglings and numbness, and sweating of the skin, flushes of heat and shivers of cold, emotional explosions, and a large group of hysterical symptoms. It can also lay claim to being an important factor in the causation of insanity. Yet, contrary to the prevalent lay and professional belief, how rarely can true uterine hæmorrhages or other uterine discharges be traced to the climacteric as a cause in itself. Yet many a poor woman has lost her health, her life, indeed, by her own and her physician's traditional belief, that her hæmorrhages or other vaginal discharges are critical and due to the "change-of-life," as it is popularly called—a misnomer which too often leads to indolent diagnosis and slovenly therapeutics.

What physician of any practice has not been called in to see some wretched sufferer, whose health has been crippled for months, or even for years, by hæmorrhages or by other discharges from the sexual organs, which have been attributed to the "change-of-life" by her friends, or—what is more inexcusable—by the successive physicians whom she has consulted? To the shame of the latter, they may not have made even a digital examination; yet a polypus or a fungoid degeneration of the endometrium, or a uterine fibroid, or a cancer of the cervix has been found by a more alert man, who does not believe in climacteric omnipotency. Never can I forget a case—not the only one—of a beautiful woman, beloved by a large circle of friends and surrounded by every luxury that wealth could furnish, who was allowed by her physician to bleed almost literally to death. Why? Because a polypus, being at first intra-uterine, was not recognized, and because her age justified, in his opinion, the diagnosis of "change-of-life." This diagnosis having been made, no other vaginal examination was ever thought of by this physician. But when he was discharged and another one was called in, the latter found the polypus dangling in the vagina. She was bedridden and as translucent as alabaster when I twisted off the growth. The hæmorrhages did not return, but neither did her health, and she died a few months later quite suddenly and very unexpectedly.

In other cases, by the careless indolence of the physicians, begotten by this traditional belief in climacteric influences, I have been compelled to undeceive some poor woman and break as gently as possible to her, that the flow which she had joyfully accepted as a return of her monthly periods, and which she has mistaken for rejuvenescence, is the sure token of an incurable and far advanced cancer of the cervix.

I have learned to unlearn the teaching that woman must not be subjected to a surgical operation during her monthly flux. Our forefathers, from time immemorial, have thought and taught that the presence of a menstruating woman would pollute solemn religious rites, would sour milk, spoil the fermentation in wine-vats, and do much other mischief in a general way. Influenced by hoary tradition, modern physicians very generally postpone all operative treatment until the flow has ceased. But why this delay, if time is precious and it enters as an important factor in the case? I have found menstruation to be the very best time to curette away fungous vegetations of the endometrium, for, being swollen, then, by the afflux of blood, they are larger than at any other time, and can the more readily be removed. There is, indeed, no surer way of checking a menorrhagia or of stopping a metrorrhagia than by curetting the womb during the very flow. While I do not select this period for the removal of ovarian cysts, or for other abdominal work, such as the extirpation of the ovaries, of a kidney, of breaking up intestinal adhesions, etc., yet I have not hesitated to perform these operations at such a time, and I have never had reason to regret the course. The only operations that I should dislike to perform during menstruation would be those involving the womb itself—such as the removal of a uterine fibroid, or a partial or a complete hysterectomy, and the various operations for uterine cancer, etc. This exception is based upon the danger of hæmorrhage arising from the increased vascular tension and pelvic hyperæmia, which exist during menstruation. This is well shown in fibroid tumor of the womb, in which this increased vascularity causes a corresponding increase in the size of the tumor itself. For obvious mechanical reasons it

would also hardly be wise to sew up the torn cervix of a menstruating womb.

I have learned to unlearn that anteflexion and anteversion in themselves—that is to say, as displacements merely, and without narrowing of the uterine canal—are necessarily pathological conditions of the womb. Text-books speak of them as such, and exhibit many ingenious forms of pessaries devised to rectify these so called displacements. But very rarely indeed do I have to resort to them, and then only to a stem-pessary in anteflexions; for I find in almost every virgin or every barren woman that the womb in varying degrees is either bent forward or is tilted forward, and is apparently resting on the bladder. The mistake made, as I have more elaboratively shown in my *Lessons in Gynecology* is in attributing to this natural position of the womb the various forms of pelvic trouble, especially that of irritability of the bladder, to which women are so liable. But the sympathy between the brain and the bladder is a remarkably close one—so close, indeed, that some physiologists contend that "every mental act in man is accompanied by a contraction of the bladder." The irritability of the bladder thus becomes one of the first symptoms of nervousness, to which everyone is liable. Many a lawyer before pleading an important case, and many a clergyman before delivering a discourse, is compelled from sheer nervousness to empty his bladder. So it is with the lower animals, which, when frightened, micturate involuntarily. A nervous bladder is then one of the earliest phenomena of a nervous brain—for nervousness means a deficient control of the higher nerve-centres over the lower ones—a lack of brain-control. Now, a hysterical girl, or a woman whose nervous system has given way under the strain of domestic cares, consults the physician for such ordinary symptoms of nerve-exhaustion as wakefulness, utter weariness, a bearing-down feeling, backache, and, perhaps, above all, an irritable bladder. Upon making a digital examination, he usually finds the fundus of the womb resting on the bladder, where it naturally should rest. At once he jumps to the conclusion that the whole trouble is due to pressure of the womb on the bladder—viz., to the existing natural anteversion or to the anteflexion, as the case may be. Enticed away by the vesical lapwing from the bottom factor—the shattered nerves—he now makes local applications, and racks his brain to adapt or to devise some pessary capable of overcoming the supposed difficulty, heedless of the dilemma that the upward, or shoring, pressure of the pessary on the bladder must be greater than the counter, or downward, pressure of the womb, to which he attributes the vesical irritability.

In the lying-in chamber the fear of septicæmia will ever haunt me, but I have long since abandoned the idea cherished by that class of waistless and witless nurses, now happily obsolescent, that the parturient woman is to be swathed like a mummy and to be kept as immovable. What earthly harm can accrue to a woman after a natural labor if she turns over from side to side, sits up in bed, or even gets up to use the commode, if she feels like it, I cannot see. Natural labor is a physiological process, not a pathological one, but tradition has thrown around the lying-in bed a glamour of mischievous sentiment.

In relation to this let me express my disbelief that mammary abscess comes from "caked" breasts, or from breasts over-distended from a secretion of milk too great for the infant's needs. Mammary abscess, in the suckling woman comes, in my opinion, from cracked nipples, and from cracked nipples alone. In proof of this let me ask my readers if any one of them has ever had a case of mastitis after a miscarriage, or one of gathered breast following a stillbirth—always provided the breasts were let pretty much alone so far as pumping and sucking are concerned. Under these circumstances the unsucked and unpumped breast will swell up and grow painfully hard, but it will not inflame or suppurate. Let me not be understood as saying that an overdistended breast should not be relieved by sucking or by pumping; but the means employed for this relief must be so sparingly used, and at such long intervals, as not to crack the nipples. This immunity from mammary abscess after miscarriages and stillbirths is attributed by the physician to his local applications of belladonna, or of other milk-drying drugs. But it comes from the absence of the exciting cause of cracked nipples—the sucking child.

Long ago I came to the conclusion, that the womb, like the nose, has its own secretions; and that, because the cervical canal is stopped up with mucus, it is not to be treated any more harshly than a stopped-up nose. I was led to this belief from seeing very many cervical canals wholly closed up, even destroyed by the remedies applied to get rid of this mucus. Then again I found that, just as the nose secretes abundantly under the stimulus of the emotions, so the womb secretes more actively under a stimulus conveyed to impressionable nerves—so much so, indeed, that leucorrhœa is a common adjunct to nerve-prostration, and is then cured by the cure of its cause. This nasal analogy led me soon to think that even uterine catarrhs are not of such paramount importance as to merit heroic treatment, and that metritis and endometritis, in so far as symptoms are concerned, are often idle words. The mucus of a uterine catarrh is in quality very much the same as the mucus of a nasal catarrh, and

its secretion is in itself no more weakening. It is not a disease in itself, but is merely the symptom of a disease. It is not, therefore, that highly vitalized fluid, the loss of which, according to the traditional belief of the great majority of physicians, and of all women, saps the very citadel of life, brings on decrepit and premature old age, and hastens its victim to an untimely grave. This widespread error is a relic of mediæval ignorance, which believed in the existence of two seeds—the male and the female semen—and their admixture to insure conception. Hence leucorrhœa has erroneously come to mean pretty much the same thing as spermatorrhœa—a belief fostered by cunning quacks, who know how largely sex and sexuality make up our being and influence our credulity.

As a corollary to this, let me add, that I have wholly freed myself from the belief that cellulitis is at the bottom of most female ailments, and that the hot-water douche is its cure-all. My experience teaches me that, save in some cases of active congestion or of acute inflammation of the pelvic organs, the hot douche is of questionable utility, and that its indiscriminate employment has done far more harm than good, especially when continued for any length of time. I cannot withhold the opinion that from its use both ovaritis, salpingitis, and peri-uterine inflammation have actually been set up by the overheating and the subsequent chilling of the pelvic organs. The crucial test of surgical research which cannot be gainsaid has shown that cellulitis is almost a myth, and that what have long been deemed exudation tumors and inflammatory deposits in the areolar tissue, are tubal and ovarian lesions.

I have learned to unlearn the idea—and this was the hardest task of all—that uterine symptoms are not always present in cases of uterine disease; or that, when present, they necessarily come from the uterine disease. The nerves are mighty mimes, the greatest of mimics, and they cheat us by their realistic personations of organic disease, and especially of uterine disease. Hence it is that even seemingly urgent uterine symptoms may be merely nerve-counterfeits of uterine disease. I have, therefore, long since given up the belief, which with many amounts to a creed, that the womb is at the bottom of nearly every female ailment.

Nerve-strain, or nerve-exhaustion, comes largely from the frets, the griefs, the worries, the carks and cares of life. Yet, although the imagination undoubtedly affects it, it is not a mere whim or an imaginary disease, as all healthy women and most physicians think; but it is the veriest of realities. When some flippant talker or some slipshod thinker scoffs at nervousness as a sham disorder, I say to him: "Can the bribe of a principality keep you from blushing when you are ashamed, or from blanching when you are afraid? Under the flitting sense of shame or of fear these vasomotor disturbances are momentarily beyond your control; and so they are in the nervous woman, whose vital organs are, as it were—not transiently, but—perpetually blushing and blanching under deficient brain-control over the lower nerve-centres."

Strangely enough, the most common symptoms of nerve-disorder in women are the very ones which lay tradition and dogmatic empiricism attribute to womb-disease. They are, in the order of their frequency, great weariness, and more or less of nervousness and of wakefulness; inability to walk any distance and a bearing-down feeling; headache, nape-ache, and backache; scant, or painful, or delayed, or suppressed menstruation; cold feet, and an irritable bladder; general spinal and pelvic soreness, and pain in one ovary, usually the left, or in both ovaries. The sense of exhaustion is a remarkable one; the woman is always tired; she passes the day tired, she goes to bed tired, and she wakes up tired, often, indeed, more tired than when she fell asleep. She sighs a great deal, she has low spirits, and her arms and legs become numb so frequently that she fears palsy or paralysis. There are many other symptoms of nerve-strain, but since they are not so distinctively uterine, and, therefore, not so misleading, I shall not enumerate them.

Now, let a nervous woman, with some of the foregoing group of symptoms recount them to a female friend, and she will be told that she has womb-disease. Let her consult a physician, and ten to one he will think the same thing and diligently hunt for some uterine lesion. If one be found, no matter how trifling, he will attach to it undue importance, and treat it heroically as the peccant organ. If no visible disease of the sexual organs be discoverable, he will lay the blame on the invisible endometrium or on the unseeable ovaries, and continue the local treatment. In any event, whatever the inlook or the outlook, a local treatment is bound to be the issue.

Until my eyes were opened to the harlequin tricks of the nerves, I have repeatedly made the same mistake, and I now see it made over and over again by other physicians. To give but two recent instances out of very many:

Not long ago a lady was sent to me by a very intelligent physician to have a cervical tear repaired. She had been seen by several physicians, all of whom had treated her locally, and all had concurred in the opinion expressed by my friend. Her most pronounced symptoms were insomnia, unending weariness, excessive nervousness, great dread of being alone, severe bearing-down, painful locomotion, constant backache, and an extremely irritable bladder which gave her no peace day or night.

She had in addition most of the canonical uterine symptoms. Being sure that a comparatively trifling tear of the cervix could not give rise to so many exacting symptoms, although she herself attributed them to this cause, I closely cross-questioned her, and soon discovered the source of the mischief. After a rather difficult labor—her sole one—she had given birth to a still child. This was a great disappointment, yet she was convalescing naturally, when a great conflagration broke out in her city. After destroying most of this city it swept onward toward her house. Her valuables were hastily packed up, and she was bundled up ready to be carried away at a moment's notice. Fortunately the fire was put out at the second house from hers. Since then she had never been well.

It was not the cervical tear that had wrecked her health, but disappointed motherhood, and the noise, the tumult, the fear, the long-drawn-out agony of suspense.

The second case gave the following history:

She was aged forty-two years, and was the mother of one child, now twelve years old. She had sharp pain in the right ovary, burning aches in the left one, and difficult locomotion. A sensating of tingling, prickling, and stinging heat pervaded her whole left side. Her left eye had wavering vision, as if she were looking through heated air. The catamenia, formerly scant and painful, were replaced by an abundant leucorrhœa. Her bladder was irritable and needed emptying day and night. She was tired all the time, lay awake most of the night, and her sleep was troubled by distressing dreams. A well-known oculist had cut the muscles of her eyes, several physicians had treated her locally off and on for many years, and she was now sent to me to decide the question of the removal of her ovaries. The womb lay in the first stage of retroversion, there was some endometritis, and the left ovary was tender and reachable. Finding, as in the foregoing case, that her symptoms were out of all proportion to the local lesions, I suspected nerve-trouble, which her history confirmed. Ten years ago, while sailing with her husband across a lake, a storm overtook them. The boat filled with water and, after a desperate struggle, they barely reached the shore. Two years later her nerves, still much shaken by this narrow escape from drowning, received another shock. A burglar broke into her home, and her husband had, in her hearing, a fierce and noisy hand-to-hand fight with him. One more year passed, and she met with a railroad accident, in which twelve persons were killed, but she was uninjured. This final shock completely shattered her nervous system, and she was plainly suffering from a sore brain, and not from sore ovaries. In one word, it was the old, old story of wounded nerves counterfeiting a wounded womb.

I have learned yet another trick of the nerves: that when riotous from being under-fed, from overwork, or from lack of discipline, they billet themselves, like an insolent soldiery, on some maimed organ and hold high revel there. For instance, a woman, hitherto in perfect health, may have an adherent or a dislocated ovary, or a torn cervix, or a narrow cervical canal, or a slight displacement of the womb—lesions which may have given her no appreciable trouble whatever. But let her nervous system become unstrung, and at once, through disturbances in the circulation both of the nerve-fluid and of the blood-fluid, there set in vesical, uterine, or ovarian symptoms, which may indeed reach so exacting a pitch as to demand a local treatment. Nor are the sexual organs the only ones thus affected. Every weakened organ in the body is liable to such functional outbreaks. The stomach rejects its food, the bowels either refuse to act or else they are very loose, the heart loses its rhythm and beats irregularly, the vocal cords relax and the voice cannot be raised above a whisper, and almost every sphincter muscle in the body behaves as if it were insane. I have known a woman in her nervous attacks to become as jaundiced as if she had the liver of a Strasburg goose. The yellow color was fugitive, but it lasted longer than the emotion that caused it. Even the eyes, which before may have exhibited to their owner no visual defect, now blink painfully at the light or may cause violent headaches, which glasses alone can allay. In the following case various organs were thus affected:

An unmarried lady in splendid health and with a magnificent physique, had unusual muscular strength, which she was fond of testing. One day, while wrestling with her brother, which she often did, she felt something give way in the pelvis, and shortly after this her health began to fail. Her monthly periods, hitherto painless, now gave her acute suffering, and a persistent leucorrhœa soiled her linen. The left ovary throbbed with a constant ache, walking became painful, the bladder grew irritable, and the stomach began to reject its food. From sluggish circulation, local congestions took place, particularly in the head and in the pelvis. Thus, when she stood up, the pelvic organs seemed to fill up with blood and painful pelvic throbs beat time with her pulse. From these she got relief by sitting with her knees raised up, or by lying with her feet higher than her head. Soon insomnia, photophobia, and dreadful headaches set in. These were followed by illusions when her eyes were closed, which vanished when she opened them. She heard imaginary conversations and saw unpleasant sights. She became morose and irascible, and kept much by herself; in one word, her mind hovered on that ill-defined borderland between sanity and insanity.

The wrestling episode and her many orthodox uterine symptoms misled every one, including herself, her family, and several physicians, who attributed everything to uterine disease and treated her accordingly. She had much local treatment of the usual kind, and more for supposed anteflexion. Getting no better, she travelled many miles to con-

sult me. My examination of her revealed merely glairy mucus in the cervical canal, some tenderness over the left ovary, which was slightly displaced, and the natural anteflexion of a virginal womb. These lesions were too trivial to account for her lamentable condition, and I looked to her history for an explanation. This clearly satisfied me that she was suffering from nerve-breakdown. This diagnosis was a great surprise to her and to her mother, who accompanied her; but, notwithstanding her contrary convictions, she entered my private hospital. With the exception of a few douches of corrosive sublimate for the leucorrhœa, her uterine organs were let severely alone, and she was treated merely for her nerves. Her friends were greatly dissatisfied with this treatment, and at their instance a near medical relative wrote me a letter in which, after criticising my treatment, he urged upon my attention the wrestling match and the uterine character of the symptoms. At the end of six weeks she left me very greatly improved in every respect, but as her headaches still troubled her more or less, I asked Dr. de Schweinitz to examine her eyes. He found some astigmatism in one eye, and "the highest degree of hypermetropia which he had ever seen, excepting in two other cases." Suitable glasses remedied these defects, and she afterward progressively improved—so much so, that eight months later I received from her a most grateful letter of thanks. Further, the physician himself who had criticised my treatment of her, wrote me quite recently, that he was about to send me a patient with analogous symptoms, who had been unrelieved by a long course of uterine treatment.

Just as headache does not necessarily mean brain disease, so ovary-ache does not necessarily mean ovarian disease. Yet time and again—and I say this deliberately—have ladies been sent to my private hospital to have their ovaries taken out, when the whole mischief had started from some mental worry. Their ovaries were sound, but their nerves were not, and no operation was needed for their cure. So misleading, indeed, are the symptoms of a jaded brain or of other nerve-strain, under the uterine livery in which they are often clad, that I have recently known a jilted maiden to be treated by a cup-and-stem pessary, and a bereaved mother to be douched and tamponned and cauterized for a twelvemonth. Such cases, even when accompanied by actual uterine disease, are not bettered by merely local treatment. Nor are medicines by themselves of much avail. What they need is massage, perhaps electricity, and that freedom from care which strict seclusion gives. Hope should be infused into every case, and, above all, there must be imported into it the personality of the physician. It was not the staff of the prophet that awakened the dead child; but death was quickened into life when the prophet threw himself upon its body and breathed into it of his own intense vitality.

As the outcome of much that I have learned to unlearn, I have arrived at this very short gynecological creed: I believe that the physician who recognizes the complexity of woman's nervous organization and appreciates its tyranny, will touch her well-being at more points and with a keener perception of its wants, than the one who holds the opinion that woman is woman because she has a womb.

TUBERCULOUS DISEASE OF THE TARSUS.[1]

BY JOSEPH RANSOHOFF, M.D., F.R.C.S.,
PROFESSOR OF ANATOMY AND CLINICAL SURGERY IN THE MEDICAL COLLEGE OF OHIO, CINCINNATI.

Among the joints affected by the tubercular process, those of the tarsus are involved in about ten per cent. of all cases. If in the present paper, I nevertheless venture to limit my remarks to this somewhat neglected field of joint-surgery, it is for the following reasons: (1) Because in no other portion of the skeleton, with the possible exception of the wrist, is disease so liable to spread from part to part, assuming a progressive type and generally terminating only after a number of years with partial or complete loss of the affected parts; (2) because in tarsal disease the influence of age on the progress and termination of tuberculosis of bone finds an excellent illustration; and (3) because in disease of no other part of the skeleton are the questions of how and when to operate, if operation be at all desirable, more difficult to answer.

Tuberculous disease of the tarsus, as commonly encountered, presents itself as an infiltration limited for a longer or shorter period of time to a single bone of the anterior or posterior row. Even here it appears to have a preference for certain bones, the cuboid of the anterior and the os-calcis of the posterior row being, in my experience, most frequently primarily involved. The greater weight brought to bear on these bones in walking, and their position, exposing them to injury, may account for this preference which doubtless exists. The extent of the joint-connections of a bone or a part of a bone, which is the seat of the disease, becomes a direct index of the rapidity of its extension. Thus the most favorable cases of the appended table were those in which the disease was limited to the os-calcis and the posterior calcaneo-astragaloid joint. A further reason for limitation to the heel-bone is in the large surfaces below, posteriorly, and on either side which are uncovered by ligaments and, therefore, permit the early evacuation of abscesses, the absence of subligamentous tension preventing the spread of disease. Far less frequent is extension forward toward the calcaneo-cuboid joint or the anterior calcaneo-astragaloid joint and its prolongation between the

[1] Read before the Mississippi Valley Medical Association, Louisville, October, 1890.

astragalus and scaphoid. When the latter direction has been taken the disease may easily spread around the astragalus and involve the ankle, or, affecting the scaphoid, may extend into the common tarsal sac. It is not until late in the disease that such extension takes place. In the case of a boy of eight years the disease remained limited to the calcaneum, notwithstanding one curetting done in New Orleans and another by myself two years later. In another case the disease remained limited even after five years.

In disease of the anterior tarsus the process is less likely to be localized. Made up of small bones, covered on many sides by cartilage, ensheathed in short and unyielding ligaments, the anterior division of the tarsus is an admirable place from which the disease may spread from bone to bone and from joint to joint, until each of the many is involved. The synovial membranes, if not primarily affected, are early filled with fungoid growths. Therefore the tumefied spindle-shaped appearance of the foot usually gives evidence of the nature of the disease long before the presence of sinuses makes the diagnosis certain. Adding to the complications of anterior tarsal disease is the primary or secondary involvement of more or less of the metatarsal bones. In at least two of the cases of the accompanying table the disease began in the metatarsus and remained localized until curetting was done. In the last case, recently operated upon, it could not be determined whether the primary nidus was in the cuboid or fifth metatarsal. When the area of disease was exposed it was found that the whole of the fourth and fifth and part of the third metatarsal were implicated. Finally, cases like that of John A., of the table, are encountered, in which every bone and every joint of the anterior and posterior divisions is involved, and the ankle-joint itself has not been spared. The shapelessness of the foot, the multiplicity of the sinuses, and the extent of bone denudation, as demonstrated by the probe, leave no doubt as to the wide extension of the disease.

The question presents itself, Is tarsal disease ever recovered from without operative interference? Only twice have I witnessed so fortunate a result; once in the case of a child with multiple sinuses leading to the anterior tarsus, and once in an adult, seen with Dr. Ravogli, in whom a very tortuous sinus leading to the astragalus closed permanently, leaving the foot with practically perfect function.

With few exceptions cases of tarsal disease, when pronounced, follow a tedious course, not for months, but for years. Except in two of my cases, in which death resulted from general tuberculosis, from two to five years elapsed before the patients were restored to usefulness, and that minus one foot or with a more or less deformed foot. If the chronological record of treatment of cases of tarsal disease be scrutinized, it will be found the same in each: Six months devoted to embrocations, massage, the ice-bag or immobilization; six months with confinement to room or bed and the opening of abscesses; six months or a year devoted to watching the results of repeated attempts to cure by curetting; six months or a year given to more or less complete excision or amputation, or both. The adult with tarsal disease is deprived of three or four years of usefulness, even if recovery ensues. But in adults a fatal issue is not at all uncommon, death resulting from general tuberculosis, toward the development of which it is more than probable that our efforts to relieve sometimes contribute.

Far less gloomy is the outlook in tarsal disease of children, since in them its tendency is greater toward localization. The resistance of the surrounding structures is less than in adults. Abscesses are therefore more readily treated, and, more than all, there is the inherent recuperative power of the tissues in early life. Curetting or the informal excision of the diseased part usually relieves the difficulty and sooner or later the child recovers with a useful foot. I have never seen a case of tarsal disease in a child that required amputation, nor do I know of such a case in the experience of my friends.

In the management of tarsal disease that of early life must therefore be nicely differentiated from that of adults. In the former orthopædic appliances, improved hygienic surroundings, and fresh-air treatment can be more readily obtained, and economy of time is not so important an element as later in life.

To curtail the miseries of an adult with tarsal disease, recourse may be had to the following measures:

1st. Scraping away the tuberculous infiltration, or *évidement* of the carious bone.

2d. To more or less formal excision of one or more of the bones of the tarsus; and,

3d. To amputation.

Is *évidement* or curetting of caries of the tarsus followed by recoveries? Certainly not often, except in children, and I have known it to do positive harm. I may be permitted to report briefly three cases in illustration:

CASE I.—Mrs. R., aged forty-two years, seen with Dr. Schneider in 1885, had for two years a sinus on the inner side of the foot leading to a carious astragalus. Though lame, she was fully able to attend to her household duties, and her general health was good. In April I scraped away what I believed to be all of the diseased portion of the astragalus and os-calcis. There was no septic infection, but the wound did not heal. During the summer, abscesses followed by sinuses, developed

over the scaphoid. The patient was now confined to bed.

On October 8th, I made a formal excision of the posterior division of the tarsus, and of the cuboid and scaphoid. The wound again failed to heal. The continuous drain on the system, the prolonged confinement, and possibly the mechanical manipulation incident to the operation, induced pulmonary disease. On January 3, 1886, amputation of the leg was done. The wound healed kindly, but six months later the patient succumbed to phthisis.

Case II.—R. M., a laborer, in the poorest circumstances, seen with Dr. Carr. No history of tuberculosis. He had been in a hospital for six months. There was fungous disease of the anterior division of the tarsus, but no sinus was present. The patient insisting on an early operation, I removed, by scraping, the greater portion of the cuboid bone. The wound failed to close. A rapid development of disease in parts untouched by the operation led me to make a formal excision of the entire anterior tarsus by lateral incisions. Five months later recurrence ensued, and within less than a year after the first operation the patient died of pulmonary phthisis. The opportunity for an amputation did not present itself.

Case III.—Ed. R., aged eighteen years, a jeweller, after an attack of scarlatina, developed caries of the first metatarsal of the right foot and of the anterior tarsus of the left. When first seen sinuses had existed on the dorsal surfaces of both feet for two years, during which time, though quite lame, he followed his vocation. The first scraping was done May 8, 1888. On February 5, 1889, excision of the anterior row of the left tarsus, the cuneiform, and the first metatarsal bone of the right foot was performed. The latter wound closed. On January 3, 1890, amputation above the ankle was performed, on account of implication of the posterior tarsus and extensive infiltration of the soft parts. Recovery was speedy, and the patient was working at his desk four months later.

Difficult as the acknowledgment is, it seems to me certain that the operation of scraping caused injury to each of these cases by disseminating the tubercular disease. The operative technique may have been at fault, although to produce ischæmia I use only the Esmarch strap without the bandage. Scraping was not performed during the acute stages; incisions were made as large as needed, and every effort was made to remove all of the diseased structures. But *évidement* has failed me and the tubercular deposits left *in situ*, increased, and were disseminated after, if not as a direct result of, the operation. Experience justifies me in holding the view that curetting in the tarsal disease of adults is an operation replete with danger.

Far more encouraging are the results obtained from early and formal excisions, particularly if the disease be limited to only a part of the tarsal framework. Until the very admirable work of Kappeller, of P. H. Watson, and, last but not least, of my friend Dr. Conner, the utility, not to mention the justifiability, of the operation was questioned. In the accompanying table cases are recorded in which one or several bones of the tarsus were excised with fair and even with good results; yet, as will be seen in several, probably because they were done at a later period, the final results were unfavorable. Excision, limited to one or two bones, is practically devoid of danger, and the early removal, particularly of the anterior tarsus, where the disease is oftenest found, leaves a shortened foot, but a limb of normal length.

Concerning the best method of operation there should, in my judgment, be no question. The unilateral or bilateral incisions, though they save the tendons, afford but a poor opportunity to inspect the field of disease, and if all of it is removed, it is largely due to good fortune. On the other hand, by a free incision directly across the dorsum dividing the tendons, an inspection of the entire field of operation is permitted, and every vestige of disease can be removed. If thought best, one or two longitudinal incisions can be made over the metatarsal bones, and as much of the bones as need be can be removed. In one case that was operated upon the wound healed by primary union, and three weeks after the operation there was good motion of the toes. This and another of my cases has caused me to doubt the necessity of suturing the tendons. Unless the tendons are looped before division, their suture after the excision is extremely difficult, the upper segments being so retracted in their sheaths that attempts to withdraw them generally fail. It is probable, however, that when tendon-suture is practised a more useful foot is retained. In England, Holmes and Wright favor this dorsal incision, and in Germany Bardenheuer reports nineteen such operations, yet in three of them death resulted from general tuberculosis.

But removal of the whole or a greater portion of the tarsus is attended by a very considerable danger to life. According to Conner, the death-rate under fifteen years of age is 6.67 per cent., between fifteen and twenty-five years 10 per cent., and over twenty-five years 27.27 per cent. The latter mortality is, in my judgment, greater than that of amputation through or above the ankle. Unfortunately, as against this increased risk of life and the greater duration of treatment from late excision, there is no proportionately increased guaranty of immunity from recurrence. Even with the advanced operation of Wladimiroff-Mikulicz, the hope that a definite cure could be obtained because the operation is performed in healthy tissue has been frustrated. In five of the cases of Fisher, four of Zesa's, and one of Rose's recurrence ensued.

From what has already been stated, it is evident

that the third operative recourse in tarsal disease, namely, amputation, should, in my judgment, be resorted oftener and earlier to than has usually been done. In other words, it appears to me that there is a limit to the usefulness of conservatism in advanced disease of the tarsus of adults, and that the preservation of a deformed foot is hardly worth the sacrifice of three or four years of active life. Here, as elsewhere, every case is a problem, the solution of which must be largely influenced by the sex, vocation, social position, hygienic surroundings, and general condition of the patient.

Name and age. Years.	Date.	Duration of illness.	No. of operations.	Curetting.	Result.	Excision.	Part removed.	Result.	Amputation.	Result.	Remarks

Conclusions.—Although the number of cases here tabulated is not large, a few deductions can be made. Of 30 operations made for tarsal disease there were 15 of *évidement*, of which but 2 were successful, and these were children. In 6 the curetting was followed by an exacerbation of the previous difficulty. Of the 12 excisions, 4 were primary, and in 3 the operations were made before sinuses had formed. In these primary operations the repair was more rapid than in those in which curetting had previously been done. Four of the excisions were failures, in 3 from recurrence of the disease, and in the fourth from the uselessness of the foot. While no deaths were directly attributable to tarsal disease, death resulted in 2 of the cases from general tuberculosis, which might have been avoided by a primary excision, or more certainly, by early amputation.

THE TREATMENT OF CROUP WITH SPECIAL REFERENCE TO TRACHEOTOMY AND INTUBATION OF THE LARYNX.[1]

BY H. R. WHARTON, M.D.,
SURGEON TO THE CHILDREN'S HOSPITAL OF PHILADELPHIA.

A FEW years ago I read before the Philadelphia County Medical Society a paper upon "Tracheotomy in Diphtheritic Croup." Since that time my experience with the operation has been considerably enlarged, and I have also had some experience with the more recently introduced operation of intubation of the larynx in the treatment of such cases.

I think that the vast majority of cases of croup coming under my observation were diphtheritic, but I have also seen a number of patients in whom the disease might be considered as true or simple croup, which seemed to me to be the result either of catarrhal laryngitis or of œdema of the larynx.

The symptom calling for operative interference

[1] Read before the Philadelphia County Medical Society, November 12, 1890.

in croup is a form of obstructive dyspnœa characterized by suppression of the voice, great difficulty of inspiration, lividity of the lips, depression of the supra-sternal and supra-clavicular spaces, sinking in of the lower part of the chest, inability to breathe while in the recumbent posture, restlessness and inability to sleep except at very short intervals. When these symptoms are present and are increasing, I think that some operative interference is urgently indicated.

I would here call attention to the dyspnœa which is often observed in patients suffering from diphtheria, pneumonia, capillary bronchitis, or congestion of the lungs, and which differs from the form of obstructive dyspnœa that I have just described in being accompanied with very rapid respiration, and in failing to present the symptoms so marked in obstructive cases.

These cases I am often asked to see with regard to the question of surgical interference, but in such cases there is manifestly no indication for operative treatment, as the dyspnœa results from diminished air-space in the lungs, and not from a localized obstruction high up in the air-passages.

Inability to sleep I consider an important symptom in deciding as to the advisability of operative interference, whether by tracheotomy or by intubation of the larynx. This is a clinical observation which I made some time ago, and which Mr. Hewitt explains as follows: During ordinary sleep the activity of the diaphragm is lessened, the centres which preside over it enjoying comparative rest, while in obstructive dyspnœa the patient, to a great extent, depends upon the increased action of the diaphragm, so that natural sleep is generally impossible, except at short intervals.

Although the symptoms of dyspnœa may be marked and increasing, if the patient is able to sleep for half an hour or an hour at a time, I am inclined to employ a method of treatment, which I will describe, before I resort to either tracheotomy or intubation.

When I see a case of croup comparatively early in the disease when the symptoms are not so urgent as to demand immediate operative interference, I also employ this course of treatment which, I feel sure, often averts the necessity of operative procedure. If the case be one in private practice, I have the patient put in a room in which there is a stove, and upon this is kept constantly boiling a large pan of water to moisten the air. If the room is heated by a furnace, I use a gas-stove or alcohol lamp to heat the water and accomplish the same purpose.

I give the patient internally:

R.—Carbonate of ammonium	2 grains.
Syrup of senega	10 minims.
Mucilage of acacia	2 drachms.—M.

To be given every two hours unless the patient vomits, in the event of which I diminish the frequency of the dose.

I also frequently employ a steam atomizer, in the receiver of which is the following solution:

R.—Sodium carbonate	1 to 2½ drachms.
Glycerin	2 ounces.
Water sufficient to make	4 "

This solution was first recommended by Mr. Parker, of London.

If the patient is old enough to be manageable he should inhale the vapor from this for a short time, at intervals of fifteen or twenty minutes. If the patient is unruly or so young as not to be able to inhale the vapor, I have the bed converted into a tent by the use of a few sticks and a sheet, under which the steam atomizer is kept in operation, the spray being directed as near to the mouth as possible. It is surprising how willingly a comparatively young or unmanageable child will take the mouthpiece of the atomizer into his mouth and inhale the vapor after he has once done so, and has experienced the relief which follows its employment. If there is reason to think that the case is one of diphtheritic croup the patient is given in addition either calomel in small doses, bichloride of mercury, or any other drug which may be considered advisable.

Of the utility of this form of treatment in the early stages of croup, I have the highest opinion, for under its use I have frequently seen cases which were beginning to exhibit symptoms of marked dyspnœa gradually improve and cough up pieces of membrane or masses of muco-purulent matter, and in twelve or twenty-four hours be entirely relieved of dyspnœa and subsequently make an uninterrupted recovery.

My experience therefore leads me to recommend some such form of treatment in the early stage of croup if extremely urgent symptoms are not present, and I do not feel that everything has been done before resorting to operation unless this plan has been instituted.

If in spite of the treatment which I have described the symptoms of dyspnœa become more urgent and assume the characteristics which I have previously pointed out, I then consider that operative interference is indicated, bearing in mind the fact that an operation—either tracheotomy or intubation—is only a mechanical procedure to relieve the dyspnœa. Personally I am not in favor of very early operation, for as I have before stated, under the treatment described I have often seen the dyspnœa relieved and recovery follow.

If the symptoms presented are of such a nature as to call for surgical interference to relieve the dyspnœa, I consider several points in deciding as to which operation to employ. If the dyspnœa has

existed for some days and is increasing; if there are patches of false membrane on the pharnyx; and if the patient exhibits marked constitutional evidences of diphtheria, I am inclined to recommend tracheotomy in preference to intubation. If, on the other hand, the dyspnœa has existed for a short time only, and if there is no false membrane in the pharnyx or sputa, although the dyspnœa may have increased rapidly, I generally recommend intubation, for it is in these rapidly-increasing cases of dyspnœa that intubation is an especially useful procedure.

The reason of my preference for tracheotomy in cases of slowly-developing dyspnœa is that in these there is usually a well-organized membrane in the larynx and the trachea, which may extend below the lower end of the intubation tube, or which may be pushed in a mass before the tube, suddenly occluding the trachea and arresting the entrance or exit of air. So much do I fear this accident, which has occurred in the hands of some surgeons, that I never introduce an intubation tube without having at hand the instruments necessary to perform tracheotomy

I also explain to the parents or to the friends of the patient that the first operation may not relieve the patient, and that a second operation (tracheotomy) may be required, and obtain, if possible, their permission to perform the latter if it should be indicated. In cases in which there is a well-organized membrane the masses that loosen may be too large to pass through the comparatively small opening in the intubation tube, and if the tube is not forced out by the expiratory efforts of the patient or removed by the surgeon or nurse, death may rapidly ensue. For this reason I leave the string attached to the intubation tube in place for a few hours, to facilitate its rapid removal if the occasion occurs.

After a case has been intubated or tracheotomized, I do not relax the local or constitutional treatment which was previously instituted; I continue to use the alkaline spray already mentioned, and if the case progresses favorably I remove the intubation tube at the end of the third or fourth day; and if the dyspnœa does not recur I do not reintroduce it. If, however, the dyspnœa recurs in a short time I reinsert the tube, and again remove it in a few days; and the second attempt is, I find, generally successful. After removing the intubation tube I continue the use of the alkaline spray for a few days.

One of the most serious objections to intubation is the trouble in nourishing the patient due to the difficulty of swallowing fluids while the tube is in the larynx; but occasionally patients will be found who can easily swallow fluids. I usually order a diet consisting chiefly of semi-solids, such as soft-boiled eggs, corn-starch and rennet; and if there is difficulty in swallowing these, I depend largely upon nutritious enemata. Thirst can be allayed by swallowing pieces of ice. The stomach-tube may be used to introduce nourishment in case the rectum becomes too irritable to retain the enemata. In some cases by allowing the head of the child to be lower than the body, and giving liquids while in this position, it will be found that they can be swallowed without difficulty. I have found that hoarseness persists for some time after the removal of intubation tubes.

If, as sometimes occurs, intubation fails to relieve the dyspnœa, or relieves it only temporarily, I resort to tracheotomy, and I have had recovery follow in such cases. If tracheotomy becomes necessary, the operation may be performed while the intubation tube is in place, removing the tube after the trachea is opened, if it interferes with the introduction of the tracheal tube.

The details of the operation of tracheotomy are so well known that I will not repeat them. Another reason for my preference for tracheotomy in the slowly-developing cases of dyspnœa, is that by a free opening into the trachea the membrane can be removed, and if the obstruction is in either the trachea or the larynx, the opening completely relieves the dyspnœa and gives the patient a full supply of air, until the separation of the membrane in the larynx occurs.

A number of cases after either intubation or tracheotomy develop recurrent obstruction due to extension of the membrane to the bronchial tubes, or to the development of a broncho-pneumonia, and in such cases further operative treatment is useless. These cases are characterized by dyspnœa of the type I have previously described, rapid respiration being the principal feature.

I do not think that a larger number of cases can be saved by intubation than by tracheotomy: in my personal experience the larger proportion of recoveries has followed tracheotomy.

In conclusion, I would say that in intubation of the larynx we have added a valuable surgical procedure to our means of treating croup. I think it is especially to be recommended in those cases which I have described as cases of rapidly-developing dyspnœa in which the obstruction is probably due to a slightly-developed diphtheritic membrane, to œdema of the larynx, or to catarrhal laryngitis. I do not think that intubation of the larynx is an operation entirely free from danger. Intubation has the advantage of being a bloodless operation, and practically without pain, and for this reason the friends of the patient will often consent to intubation when they would refuse to have tracheotomy performed.

The management of cases after intubation is comparatively easy, with the exception of the difficulty of nourishing the patient.

In very young children, in whom the results of tracheotomy are not so favorable, I think intubation should first be employed, unless some contra-indication exists.

Tracheotomy generally completely relieves the dyspnœa, and allows the surgeon to clear the trachea of membrane, and is, therefore, to be preferred in slowly-developing cases of dyspnœa in which there is apt to be present a well-developed diphtheritic membrane in the larynx or trachea. If carefully performed, there is comparatively little risk in the operation itself. Patients after tracheotomy have little difficulty in taking a full supply of liquid nourishment, which certainly is most urgently indicated in an asthenic disease like diphtheria, and it is in this disease that the operation is most frequently called for.

EPIDIDYMITIS CAUSED BY ABDOMINAL STRAIN.

By EDWARD MARTIN, M.D.,
SURGEON TO THE HOWARD HOSPITAL; ASSISTANT SURGEON TO THE HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA.

Although it is undoubtedly true that the vast majority of inflammations involving the epididymis are dependent upon the extension of gonorrhœal infection through the vas deferens, it is well recognized that epididymitis may be produced by a number of other causes; thus traumatism, gout, rheumatism, malaria, and tubercle may all provoke a local inflammation of great intensity in this region.

In addition the physician will occasionally meet cases in which the possibility of all these causes is positively denied, and yet in which the symptoms of an active inflammation of the epididymis are present. The patients usually ascribe this condition to a strain or a violent lifting effort.

It is certainly true of the writer, and probably of the vast majority of practitioners, that such statements have been received with absolute incredulity, and that the causative agent has always been regarded as a preëxisting gonorrhœa, since this affection is very commonly accompanied by a moral obliquity which seems to render a truthful narration of the history of the case impossible.

Lately, however, two cases have been observed in which the statements of the patient seemed so trustworthy that sufficient credence was given them to make a careful examination, and in one instance, at least, this was so thorough, that the possibility of all the predisposing and exciting factors mentioned above could be absolutely excluded. The history of this case is as follows:

J. T., a porter, aged thirty-six years, is a strongly-built man of medium height. His father died of consumption at the age of fifty-six years; there is no other case of this disease in the family. He has always been strong. He practised self-abuse in moderation until the age of twenty years, when he was married. From the period of puberty he has suffered from a certain amount of sexual weakness, involuntary emissions taking place on slight excitement. This was still noticed after marriage, though to a less extent than before. He has had no venereal disease. Five days before he appeared for treatment, in the evening following a heavy day's work, he suffered from pain located in the lower part of the left testicle, and at the same time swelling was observed. These symptoms steadily grew worse, the pain extending into the groin.

On examination, the right testicle and epididymis were found normal: the left testicle was slightly enlarged and was tender, but still soft and of normal consistence. The epididymis was hard, very tender, and about three times its natural size. The skin over this region was hot and red.

An examination of the urethra showed the absence of stricture; no pus could be detected upon the instruments when they were withdrawn. A careful microscopical search of the urine was made, but no pus or albumin could be found. Rectal examination showed a slightly-enlarged prostate, moderate pressure upon which produced a desire to urinate. The seminal vesicles could not be felt. The lungs were found to be normal on examination. The patient had not suffered from rheumatism or malaria.

Two days later the swelling had increased, involving the testicle; the pain on standing or walking was severe. A Langlebert suspensory bandage was applied; this gave the patient almost immediate relief and enabled him to resume his work. This treatment together with careful attention to the condition of the bowels was sufficient to accomplish a speedy cure.

In the other case observed, an opportunity to make an examination sufficiently thorough to exclude absolutely the presence of posterior gonorrhœa was not offered, hence it cannot positively be asserted that it was a case of strain-epididymitis, though the evidence on the part of the patient was as nearly conclusive as this can ever be.

In the case detailed above we have an instance of epididymitis not associated with any of the causes or conditions commonly recognized as factors in the development of the disease. Pain and swelling developed after a hard day's work; neither were especially marked at first, and the latter shortly involved the testicle to a moderate extent. Provided the examination of this patient was carefully conducted, this case alone would establish the possibility of inflammation of the epididymis and testicle following muscular effort, or what has sometimes been called primary epididymitis. This case is not, however, without ample corroboration.

Though little has been written in the English language concerning strain-epididymitis, the affection has been long recognized by French and Ger-

man writers. Thus Velpeau distinctly alludes to it, and following him we have a long list of authorities —Vidal, Curling, Gosselin, Soulé, Richet, Delomme, Coutan, Hamilton, Le Dentu, Pellier, Wagner, Englisch, Hublé, etc. All are practically agreed upon the point that independent of any distinct idiosyncrasy, violent inflammation of the epididymis may be excited by strong muscular effort, particularly when such effort calls into play the muscles of the abdominal parietes.

As to the mechanism by which such inflammation is produced there is a widespread diversity of opinion; thus by some it is held that it is due to pressure upon the vas deferens, others hold that it is due to pressure upon the veins of the cord, and still others that the injury is inflicted by violent contraction of the cremaster muscle, which by suddenly jerking the testicle against the pillars of the external ring, causes a bruising of the latter, often accompanied by a rupture of the veins. This is called by the French the *coup de fouet*, or whip-snap action.

According to Roux, the theory of compression of the cord and its veins is made probable by the existence of certain fibres which pass from the rectus muscle to the inner lip of the iliac crest. When the abdominal muscles are thrown into sudden violent contraction, these fibres participate in the motion and, in pressing the cord upward, pinch it against the fibrous circumference of the external abdominal ring.

The general consensus of opinion, however, and this is particularly the case with recent writers, strongly inclines to the theory that the cremaster muscle alone is the direct cause of the inflammation.

That this muscle is capable of very vigorous contraction cannot be doubted. Thus it is not rarely observed that direct trauma of the testicle is followed by marked retraction of this organ, so that it may be drawn into the inguinal canal, or even into the abdominal cavity. Even in severe pain, such as that which accompanies renal colic, the testicles are frequently found in close apposition to the external ring, while anyone can observe the contraction of the cremaster by noticing the motion of one or both testicles during the passage of a catheter. Certain cases of chorea of the testicle are at times observed when this organ is moved by the cremaster with considerable rapidity and violence.

Richet, while acknowledging the important *rôle* played by the cremaster, believes that the result produced by this contraction is due, in the main, to rupture of the veins produced by pressure upon them. The majority of writers strongly favor the "whip-snap" action of the cremaster, and the consequent bruising of the epididymis and testicle as the cause of the subsequent inflammation.

According to this theory, then the cause of this form of epididymitis and orchitis is precisely the same as is the case when a blow is received upon this region.

Experimentally, it is found that the violence of traumatic orchitis and epididymitis is directly proportionate to the amount of injury inflicted, and that where the trauma is at all severe there is nearly always extravasation of blood, not only beneath the fibrous tunic of the testicle and epididymis, but into the parenchyma of these organs, particularly of the latter. It is also observed that the inflammatory symptoms following direct violence do not always immediately appear.

In the form of orchitis and epididymitis under discussion, it would seem that much the same lesions occur as when these parts are bruised by external violence. That there is frequently extravasation of blood can at times be confirmed by examination. The inflammatory symptoms are marked, but come on slowly.

Although this theory as to the cause of epididymitis from muscular strain is almost universally accepted, there are several powerful arguments against it. In the first place, direct trauma, even when not of sufficient violence to excite marked inflammatory symptoms of the testicle or its appendages, is immediately followed by agonizing and unbearable pain. If the mechanism of a spontaneous inflammation were that described above, and according to the whip-snap theory the violence is just as direct as though the testicle had been struck with a club, the histories of reported cases should uniformly mention the presence of such pain. This symptom is, however, conspicuous by its absence. There is often observed a sharp, sticking sensation, or a pain of moderate severity, but never that which characterizes pain of the testicle.

Again, muscular fibres are not capable of indefinite contraction; they can shorten to a certain extent, but beyond this no diminution of their length is possible. By the time the testicle has reached the external ring, it would seem that the contractile power of the cremaster must have practically reached its extreme limit, and hence it is difficult to conceive how this muscle is able to exercise sufficient pressure upon the testicle to produce serious lesions by bruising it against the columns of the ring.

Upon the "whip-snap" theory alone it is hard to explain why the affection should exert such a decided predilection for the left side. Of Englisch's seven cases, in six the left testicle and epididymis were involved—the seventh was bilateral. In the case reported in this paper the left testicle was involved, and other observers concur in this observation.

There is, however, a theory, the *rationale* of which

is much more readily comprehended, and which would account for the appearances observed in at least the great majority of the reported cases.

The spermatic plexus of veins is peculiarly under the influence of intra-abdominal pressure; the vessels are provided with but few and imperfect valves; are feebly supported by the surrounding tissues, and hence are especially subject to disease. Thus varicosity of these veins is one of the most common surgical affections, and the effect of the contraction of the abdominal parietes and the diaphragm upon these dilated veins is so marked, that succussion on coughing, or straining in any way, is sufficiently distinct to simulate that of an omental hernia.

Given, then, a sudden and violent increase of pressure in these vessels, it is perfectly possible to conceive that rupture may take place, even though they be healthy; this is of course more probable if they are weakened and dilated. Such rupture would naturally take place in the cord, in the epididymis, or even in the substance of the testicle. And if the theory of venous rupture from pressure is correct, we would expect the left testicle to be most frequently involved, as veins of this side are most frequently varicose, and we would expect the pain first to be slight and gradually increase, as more blood was effused and inflammatory symptoms developed.

Now these are the very conditions which characterize inflammation of the epididymis following muscular effort, and on this basis we think we have sufficient explanation for the occurrence of this affection without attributing any causative *rôle* to cremasteric contraction, although the latter may play a subsidiary part.

One of Englisch's cases strikingly illustrates the probability of this theory. The patient, a laborer, nineteen years old, while working, suddenly felt a sharp sticking pain in the left scrotum; at the same time there was a discharge of blood from the anus. Shortly the characteristic local and general symptoms of orchi-epididymitis developed. Here effort called into play the muscles of the abdominal parietes; this increased the intra-abdominal pressure. As a result of this, there was increased tension upon the veins of the rectum or anus and those of the pampiniform plexus. Evidently some branch of the hæmorrhoidal plexus gave way under the strain, and there was free bleeding. Why it is necessary to ascribe the testicular symptoms to bruising of this organ against the columns of the external ring rather than to rupture of a vein, is not explained by Englisch.

From the cases of epididymitis under discussion it is necessary to separate carefully instances of inflammation dependent upon latent disease, such as tuberculosis and malignant tumor. Here it is not uncommon for the patient to notice first some trouble about the testicle immediately after violent exertion, though such trouble has in reality existed for some time.

It is well recognized that gonorrhœal epididymitis or orchitis is peculiarly prone to appear in those who are forced to undergo severe and prolonged labor, and that this complication develops after the disease has invaded the posterior portion of the urethra; hence an examination of the meatus for discharge is, in cases of absence of the latter, not sufficient to exclude gonorrhœa as the cause of the intra-scrotal inflammation. The urine must be carefully examined for pus, and, moreover, the urethra should be explored to prove the presence or absence of stricture.

The prognosis of epididymitis or orchitis following increased intra-abdominal pressure from muscular contraction is exceedingly favorable. The treatment consists in keeping the bowels open and in the application of those agents most powerful in causing absorption of blood-clot and inflammatory exudate, namely, moisture, warmth, and pressure. This is accomplished by a modified Langlebert bandage,[1] which I employ in all cases of epididymitis, and which has yielded uniformly satisfactory results. The bandage is made in the form of an ordinary suspensory-bandage, but less pouched than those found in the shops. The part covering the scrotum is made of mackintosh. A wedge-shaped piece is cut out from each side of this, and lacings are arranged so that the edges of this V may be brought together. The scrotum is enveloped in a thick layer of absorbent cotton, the suspensory-bandage is adjusted, and, finally, the lacings at the sides are drawn in until tight, uniform pressure is exerted on the swelling. The mackintosh prevents evaporation and keeps the parts moist, the cotton preserves the heat, and by means of the gores at the sides of the bandage the pressure can be accurately adjusted. Even in gonorrhœal epididymitis this dressing commonly enables the patient to resume his work in a few hours, and in the form of inflammation under discussion it is equally satisfactory in its effect.

From a careful study of the literature of the subject, the following conclusions seem justifiable:

1. Epididymitis, orchitis, or orchi-epididymitis, may develop as the result of violent or prolonged muscular exertion, without the intervention of any of the commonly recognized predisposing or exciting factors.

2. Such exertion as is accompanied by strong contraction of the muscular parietes of the abdomen is particularly liable to be followed by this form of inflammation.

[1] This bandage is made for me by Mr. Lenz, of Philadelphia.

3. It is commonly taught that this affection is due to a sudden and violent contraction of the cremaster muscle, which jerks the testicle upward and bruises it against the columns of the external ring.

4. The facts that the left epididymis and testicle are nearly always involved, that the first pain is usually slight, and that this affection commonly develops in those subject to varicocele, show that the inflammation is more probably due to venous bleeding occasioned by increased blood-pressure, which is in itself due to the increased intra-abdominal pressure resulting from contraction of the abdominal muscles.

5. This inflammation usually invades the epididymis, though the testicle also may become involved. The first symptom is pain of moderate severity, often felt in the inguinal region, which is followed by swelling that may not appear for a day or two. The symptoms run an acute course.

6. The treatment consists in careful attention to the condition of the bowels, and in the application of a Langlebert suspensory bandage. The patient, after the swelling has reached its height, need not keep his bed.

CLINICAL MEMORANDUM.

MEDICAL.

Death from Intra-pulmonary Injection.—The following mishap, occurring among the treatment of phthisis by intra-pulmonary injection, is interesting. During part of the writer's term of service as house physician of the Buffalo General Hospital in 1888–89, a large number of cases of phthisis were treated by intra-pulmonary injections. The medicament used was a three-per-cent. solution of beechwood creasote in oil of sweet almonds. Of this about ten minims were injected at a time into a cavity or solidified apex. In most instances the immediate effects were very encouraging. The expectoration usually decreased, and the temperature, after the slight rise caused by the operation, fell, and continued for a time nearly normal. More than fifty such injections had been made with favorable results, when the following accident occurred:

The patient was well nourished, and under tonic treatment, and the disease seemed to be in abeyance. Three injections had been made, at intervals of four days, into the left apex, followed in each instance by decreased expectoration and marked diminution of evening temperature.

The fourth injection was made by the usual method into the right apex, and the patient immediately after the procedure resumed his duties about the ward. Twenty minutes later he was seized with violent dyspnœa, which gradually became worse. He had formerly suffered from asthma, and the present attack resembled an asthmatic paroxysm. The irritation caused by the drug on the peripheral endings of the vagus seemed to afford a plausible explanation in support of this diagnosis. The usual remedies for asthma were administered, but all failed to give relief. Auscultation was rendered impossible by the violent tossing and groaning of the sufferer. About an hour and a half after the injection the patient died.

At the autopsy the right lung was found entirely collapsed, and the pleural cavity filled with air. The needle in entering the lung had passed through tissue as thin as ordinary writing-paper into an emphysematous space, communicating with a small cavity, which in turn communicated with a bronchus. After the puncture the thinness of the wall prevented it from retracting sufficiently to act as a valve, and the inspired air must have passed almost directly into the pleural cavity.

Cases of pneumothorax have been reported, following intra-pulmonary injection; but all were slight, and ended in recovery. Only one death immediately following this treatment is recorded, and in that case death was due to acute suppurative bronchitis. Had the pneumothorax been diagnosed in my case at the outset of the attack it is possible that surgical interference might have saved the patient. The condition, however, was wholly unexpected, and was not recognized by any of the physicians who examined the case.

The slight benefits following this method of treatment are, in the writer's opinion, secured at too great a risk to make the procedure advisable.

Robert T. French, M.D.

HOSPITAL NOTES.

PYELO-NEPHRITIS FROM CALCULI—GRADUAL DILATATION FOR CONTRACTED BLADDER—TRAUMATIC TETANUS.

Abstract of a Clinical Lecture delivered at Bellevue Hospital, New York.

By JOHN W. S. GOULEY, M.D.,
VISITING SURGEON.

Before presenting any patients, Dr. Gouley showed some specimens removed post-mortem from a case of prostatic enlargement and obstruction to urination, with the grave complication of a contracted bladder. He said that if the capacity of the bladder has become increased, no matter how thick the walls may be, there is a prospect that the patient will live a long time; but if its capacity is so diminished that it can hold only one or two ounces of urine, the prognosis is exceedingly bad.

The patient, from whom the specimens were removed, was admitted to one of the New York hospitals last June for cystitis, and was there subjected to the operation of suprapubic cystotomy. An India-rubber tube was introduced and secured in position, with a rubber bag attached to receive the urine. In September he was admitted to Bellevue Hospital. The man thought that the operation had given him decided relief; but this is doubtful, for a catheter retained so long in the bladder, acting as a foreign body, must have become encrusted with phosphates. After admission to Bellevue Hospital his bladder was irrigated once daily, but it was so irritable that not more than two ounces of urine could be retained. The urine was constantly voided through the urethra, in spite of the opening which had been made above the pubes for the purpose of draining the bladder.

The record states that there was no albuminuria, but there should have been some albumin derived from the pus in the urine. Absence of albumin in the urine does not, however, exclude even extensive renal disease. The patient became gradually more feeble and died during the preceding night. The kidneys, both of which were shown, were increased in size, the left being the larger. On section of the left kidney pus was found in its pelvis, and this, together with the condition of the cortical portion, afforded an excellent illustration of pyelo-nephritis. Searching a little further the cause of the existing pyelonephritis was found to be the presence of calculi in the renal pelvis, there being three stones of uric acid, one of which was five-eighths of an inch in diameter, the others were smaller. In the right kidney there was also pyelitis; but the pelvis was not so much distended, and there was no stone. The bladder was about the size of the prostate, and would hold scarcely two ounces of fluid.

The suprapubic operation was done for the purpose of draining the bladder, and yet there was no urethro-vesical obstruction, and the record shows that the urine was passed by the urethra from the time the patient entered the hospital till the day of his death. The operation was a conspicuous failure so far as draining the bladder was concerned. It is well known that where there is calculous pyelitis, and particularly where there is a pyonephritis, the most constant, and sometimes the only, symptom is referable to the bladder. The diagnosis of renal calculus is not easy, unless there is sufficient distention of the pelvis of the kidney to cause a tumor sufficiently large to be detected by the usual methods of physical examination. If a correct diagnosis had been made in this case the only proper operation would have been a nephrotomy, and had such an operation been performed it is likely that the vesical symptoms would have speedily subsided.

In cases in which there is no renal calculus, but simply a contracted condition of the bladder from some other cause, as, for instance, urethro-vesical obstruction from contraction or from prostatic enlargement, much can be done for the comfort of the patient, and in some cases a cure may be brought about by employing the method of gradual hydraulic dilatation of the bladder, just as a urethral stricture would be gradually dilated, substituting for the solid sound the dilating force of water. In carrying out this method of hydraulic dilatation the quantity which is daily injected into the bladder at each sitting is to be increased almost imperceptibly. In this way the twofold object of treatment is attained—namely, keeping the bladder clean, and at the same time increasing its capacity. After a number of weeks or months it is found that the bladder is capable of retaining very much more fluid than at first.

Case I.—Dr. Gouley then showed a patient as an illustration of this treatment. He first came to the hospital about a year ago, and is now an out-patient. When first seen his bladder was very irritable, and would not hold more than one and a half ounces of fluid. He has been treated at intervals ever since. His general health is now good and his bladder is capable of holding seven ounces of the ordinary solution used for irrigation, which is equivalent to holding eight or ten ounces of urine. Vaginal cystotomy for the relief of a similar condition in the female has been very frequently performed in recent years, but Dr. William M. Polk has stated that he has abandoned the operation, having found the method of gradual dilatation more satisfactory. Other gynecologists have also abandoned vaginal cystotomy and have substituted the more innocuous method of gradual hydraulic dilatation. This method of dilatation of contracted bladders is not new. It was recommended long ago by Civiale, but it does not seem to have been very generally adopted until lately. Fourteen years ago the speaker removed several villous tumors from the urethra of a lady already advanced in years, and supplemented the operation by dilatation of the bladder in the manner just mentioned. Before the operation urination was very frequent, occurring every few minutes, and so painful and distressing that her general health was rapidly failing. As a result of the treatment her bladder was able to hold five or six ounces of fluid and she is now enjoying a hearty old age.

Case II.—The next patient was an old man, who is said to have had urethral stenosis, which was dilated so that it now admits a No. 12 sound of the English scale, and yet he urinates every half hour. This trouble, then, is not dependent upon the diminution of the urethral calibre, but upon the condition of the bladder. On passing a soft catheter there seems to be some sensitiveness of the urethra, but the bladder, as shown by the quantity of fluid injected, holds five ounces; hence, there is no indication for hydraulic dilatation, and the treatment should consist of sytematic efforts to keep the bladder free from pus by daily irrigation. The following solution is useful for this purpose:

℞.—Bichloride of mercury	. .	5 grains.
Ammonium chloride	. .	15 "
Spirit of gaultheria	. . .	½ ounce.
Sodium borate	. . .	1 "
Glycerin	. . . . .	8 ounces.—M.

Half an ounce of the above mixture and two and one-half ounces of peroxide of hydrogen solution with seven ounces of warm water may be used for irrigating the bladder.

Dr. Gouley then referred to a case of traumatic tetanus in the ward of his colleague, Dr. Charles Phelps, which he said is a rare disease in New York. The first symptom of the disease made its appearance a few hours before the lecture. The patient is a boy, about sixteen years of age, who ten days previously was caught between cog-wheels and sustained a severe injury of the left lower extremity. Both the popliteal and peroneal nerves were injured, the former so badly that its ends could not be brought together by sutures, as was done in the case of the peroneal. On his admission to the hospital an hour or two after the injury, the wound was found to be in an exceedingly filthy condition, and was cleansed as thoroughly as was possible. No untoward symptoms were noticed until this morning, when a slight trismus or "lock-jaw" was observed. So far there has been no laryngeal spasm. This patient had already been given repeated doses of Calabar bean. Dr. Phelps says that he has had two cases of recovery from tetanus which he is inclined to ascribe to the use of the Calabar bean. The lecturer said that he also had had two recoveries, in both of which the disease had progressed until the patients presented the classical picture so vividly portrayed in Bell's *Anatomy of Expression*, and yet they

received only a little morphine and bromide of potassium. In one of these cases the patient, who was about thirty years of age, had a compound fracture of the forearm with a filthy wound; the other was a boy of nineteen years, who had a severe laceration of the foot. The speaker was once induced to amputate during the prodromic symptoms of tetanus, but this did not avert the fatal termination.

Tetanus is a rare affection in New York City, but it seems to be endemic near the eastern end of Long Island, and is quite common, particularly that form known as trismus neonatorum, in hot climates. Some very interesting researches have been made recently into the etiology of tetanus, the results of which lead the observers to the belief that tetanus is of microbic origin. Brieger has made cultures of the tetanus bacillus, and extracted in this way a ptomaïne to which he has given the name of *tetanin*, and this in solution, when injected hypodermically into small animals, has been found to produce symptoms similar to those of tetanus.

The patient before the class had neither opisthotonos nor emprosthotonos; but the slightest movement or excitement caused a facial spasm. One of Dr. Gouley's successful cases was in such a condition for three months that simply touching him was sufficient to bring on a severe spasm. In some of these cases it is necessary to resort to rectal alimentation; and if this mode of feeding be properly carried out it is not difficult to keep up a fair standard of nutrition. He once nourished a child of five or six years entirely by the rectum for thirty days. The fluid for injection should be simple—usually milk—and before each injection the rectum should be thoroughly cleansed by a simple enema. This is important; for after a while a hypersecretion of mucus follows this method of alimentation, and beef peptones and other articles of food may remain in the rectum and putrefy, until the stench of the evacuations is intolerable.

The facts that in this case the wound looks healthy and that the slough is separating, together with the mild character of the symptoms and the very moderate disturbance which the presence of so many persons seems to have produced in him, cause us to think that the disease may terminate favorably.

MEDICAL PROGRESS.

Evacuation of the Uterus after Parturition. — MME. GACHES-SARRANTE (*La Semaine Médicale*) believes that ergot should be used neither during labor nor after, as the uterus is never completely emptied during parturition, and the clots or shreds of membrane that remain may become sources of infection, and are a frequent cause of subinvolution. The author's practice is to empty the uterus completely in all cases by passing the hand into the cavity of the organ. This procedure she thinks is attended with little danger if the hand is aseptic and if care is taken to avoid wounding the uterine tissue. If the uterus is thoroughly emptied and washed out with sterilized water, hæmorrhage is immediately arrested and involution is rapid.

Treatment of Acne.—In a paper on the treatment of acne, DR. HENRY W. BLANC, of New Orleans (*Journal of the American Medical Association*, October 25, 1890), lays particular stress on the importance of keeping the digestive organs in good condition by avoiding improper food and securing a movement of the bowels daily. The comedones and pustules should be opened regularly by a lancet and comedone-compressor, and it should be remembered that scarring is less likely to result from the disease if these measures are carefully carried out than if the pustules are not interfered with. As an application, sulphur has given the author better results than any other agent. As a lotion he prefers the following modification of the well-known *lotio alba*:

R.—Potassium sulphide Zinc oxide Zinc sulphate Glycerin	of each	2 drachms.
Rose-water sufficient to make		4 ounces.—M.

Apply to the skin after having thoroughly removed the oily secretion. This application produces a sensation of puckering and dryness of the skin. It is well to alternate this lotion with the following:

R.—Precipitated sulphur	1½ drachms.
Salicylic acid	20 grains.
Fluid extract of ergot	2 drachms.
Lanolin sufficient to make	1 ounce.—M.

This should be applied morning and evening after having washed the face with water and Hebra's alcoholic soap-lotion. [Hebra's soap-solution is composed of green soap 4 ounces, dilute alcohol 2 ounces, spirit of lavender 1 drachm.] In some cases ichthyol and salicylic acid combined as follows are useful:

R.—Ichthyol	6 drachms.
Salicylic acid	40 grains.
Vaseline	2 ounces.—M.

Apply to the face night and morning.

During the treatment of acne it is important to avoid anything which irritates the skin, such as dust, frequent washing, and friction with a coarse towel. It is well to use a bland soap in order to remove the oily secretion of the sebaceous glands, or in its place the following lotion may be used:

R.—Boric acid Glycerin	of each	2 drachms.
Alcohol		1 ounce.
Ether sufficient to make		3 ounces.—M.

This may be allowed to dry upon the face, and will not attract attention.

Therapeutics of Biniodide of Mercury.—DR. C. R. ILLINGWORTH, who has so persistently advocated the use of biniodide of mercury as an antiseptic, contributes another paper upon the subject (*Provincial Medical Journal*, November 1, 1890). The salt is prepared by dissolving bichloride of mercury in a solution of potassium or sodium iodide. Locally he uses the solution in the following diseases: Ophthalmia neonatorum, 1 to 3000; gonorrhœa, 1 to 5000 or 6000; hay-asthma, 1 to 1000; alopecia, 1 to 500; scabies, 1 to 400; ringworm, 1 to 4 or 5; ozæna, 1 to 3000 or 4000; otorrhœa, 1 to 2000 or 3000; pelvic abscess, 1 to 2000 or 3000; and in the strength of 1 to 2000 to disinfect the mouth and throat

in scarlet fever and diphtheria, and the nose, eyes, and air-passages in measles and whooping-cough.

Dr. Illingworth considers the alterative action of the drug of even more importance than the antiseptic action, particularly in the treatment of inflammatory diseases of the serous membranes, such as meningitis, pericarditis, pleuritis, and peritonitis. For instance, in the meningitis of children he uses the following formula:

R.—Solution of bichloride of mercury (B. P.) . . 2 to 3 drachms.
Potassium iodide . . 7 to 15 grains.
Antipyrine . . . 15 to 30 "
Syrup. . . . . ½ ounce.
Water sufficient to make . 1½ ounces.—M.

Dose.—One teaspoonful every one or two hours.

In addition to this, 1 or 2-minim doses of tincture of aconite may be given. If convulsions occur 1-grain doses of chloral may be given every hour for twelve hours. If the temperature is very high, Dr. Illingworth gives sodium salicylate 2 grains and aromatic spirit of ammonia 2 minims with each dose of the above mixture. Pleurisy he treats on the same general plan.

Treatment of Seminal Emissions.—According to the *Canada Lancet*, BUMSTEAD recommends the following to diminish the frequency of seminal emissions:

R.—Potassium bromid. } of each 1 ounce.
Tinct. of chloride of iron }
Water . . . . 3 ounces.—M.

Dose.—One or two teaspoonfuls an hour after meals and at bedtime.

Methyl-violet (Pyoktanin) as an Antiseptic.—STILLING (*Therapeutische Monatshefte*) recommends mythyl-violet (sold by Merck under the name of *pyoktanin*) as an antiseptic, and believes that it also has the power to prevent the formation of pus. Pathogenic and other microbes, as is well known, have a great affinity for aniline colors and are rapidly killed by them. A 1-to-1000 solution of methyl-violet applied to the eye stains the conjunctiva, iris, and sclerotic, but not the cornea, blue, which disappears within twenty-four hours. The drug is practically non-poisonous, although fatal to rabbits if introduced into the peritoneal cavity in large quantities. Stilling recommends a 1-to-1000 solution of the dye in corneal ulcers, blepharitis, conjunctivitis, phlyctenulæ, keratitis, and serous iritis. He also says that it will sterilize the pus of suppurating wounds and ulcers, and that it is useful as an injection in cases of empyæma and purulent peritonitis, and as an enema in typhoid fever and dysentery. Surgical instruments may be sterilized by washing with a 1-to-10,000 solution of the drug, and wounds, after operations, may be douched with 1-to-2000 or even weaker solutions.

GARRÁ and TROJE (*Munchener medicinishe Wochenschrift*) find that methyl-violet is not poisonous, but that it has no specific antipyogenous action. Their experiments apparently show that although a solution of 1 to 1000 inhibits the development of the cocci found in pus, it does not kill them even after an exposure of twelve hours.

M. BRESGEN speaks highly of the value of methyl-violet in the treatment of diseases of the nose, and considers it especially useful in local suppurating areas of the nasal mucous membrane, such as occur after cauterization. It should be applied in solution until the tissues are of a deep-blue color, after which the nasal cavity should be plugged with methyl-violet wool for two hours. According to the author, the application diminishes suppuration and inflammation and relieves pain.—*British Medical Journal*, November 8, 1890.

The Curability of Acute Phthisis.—DR. MCCALL ANDERSON (*British Medical Journal*, November 8, 1890) divides acute phthisis into two forms, namely, acute (miliary) tuberculosis and acute pneumonic phthisis. In the latter form the disease exhibits, almost from the first, more or less extensive consolidation, most frequently of the upper lobes, leading to widespread destruction of the lung, and soon terminating the life of the patient.

Although acute phthisis is usually considered a fatal disease, Dr. Anderson has reported seven cases with five recoveries, all of which were treated by the following plan:

1. Two thoroughly-trained nurses, one for night the other for day, are indispensable. The patient must be fed upon fluid food both day and night, soup being avoided if diarrhœa is present. From two to ten ounces of whiskey daily are required in the beginning of the attack, but should be given in frequent small doses with the food.

2. At bedtime a subcutaneous injection of sulphate of atropine (from $\frac{1}{100}$ to $\frac{1}{60}$ grain) is given. This checks perspiration, acts as a sedative, indirectly helps to reduce the fever, and diminishes the secretion from the lungs.

3. Remedies to lower the temperature are given and are of the utmost importance. Some benefit is derived from permitting the patient to suck ice freely, from giving the food and drinks iced, from sponging the body with iced vinegar and water, and from using iced enemata, but our main reliance must be upon one or more of the following methods:

a. Niemeyer's antipyretic pill or powder (quinine 1 grain, digitalis ½ to 1 grain, opium ¼ to ½ grain) given every four hours, and increasing the amount of opium if there is diarrhœa: The effects of the digitalis must be watched, and if the pulse becomes very slow or the urine scanty the remedy must be omitted for a time.

b. The daily administration shortly before the time that the temperature tends to be the highest, of from ten to thirty grains of quinine, either in a single dose or in divided doses within an hour.

c. The application of iced cloths to the abdomen for half an hour every two hours so long as the temperature exceeds 100°. In applying the cold cloths the night-dress should be drawn up to the chest, a folded blanket placed under the patient, and the bedclothes arranged so that they cover the chest only, the remainder of the body being protected with an extra blanket. Two pieces of flannel are employed, each being sufficiently large, when folded into four layers, to cover the front and sides of the abdomen. One cloth is applied and covered with a dry piece of flannel, while the other is placed in a vessel of iced water by the side of the bed. The flannels should be changed at intervals of a minute.

Dr. Anderson, at the close of his paper, reports a case in which this treatment was carried out, the patient recovering.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author.

PHILADELPHIA.

SATURDAY, NOVEMBER 29, 1890.

KOCH AND HIS DISCOVERY.

THREE things may be noticed as the result of the publication of his methods by Koch. First, an extraordinary professional and popular interest; second, a flocking of medical men and consumptives to Berlin; and third, a gradually-increasing feeling of distrust both of the advantages of the so-called cure, and of the man for his refusal to reveal the secret of the preparation of the anti-tubercular fluid.

The popular interest shown is natural and proper, but the flocking of medical men to Berlin is probably useless—for those who remain behind will be kept informed of all points of interest by the cable, and those who go will be so lost in the rush that their identity will be overlooked, as the investigator and his assistants cannot supply and teach men by the thousand. Again, the trip to Berlin by consumptives is useless and absurd, both because of its dangers and ultimate uncertainty of relief, and by reason of the fact that the rule of "first come first served," so rigidly adhered to, forces a visitor to wait for weeks before he can be treated.

There is much to be said for and against Koch and his so-called cure, for there is a professional, a pecuniary, and a humanitarian side to the subject. While it is against professional ethics to hide from others anything which could be of benefit to the sick, it can be well said that anyone who makes so great a study and possible revolution in medicine should be allowed time to put every part of his work on an unalterable basis. On the other hand, if the daily papers are correct, Koch considers his work in this line finished, and is said to be preparing for studies on scarlet fever, diphtheria, and measles. This must be only partly if at all true, for the popular feeling would force both the government of Germany and the man to lend himself to the propagation of so great a boon to all nations.

In the first moment of excitement everyone felt inclined to believe much more of the possibilities of the discovery than even Koch professes to believe, and a careful and just perusal of his paper shows that he is as conservative and careful in his claims for it as in his researches. He particularly urges the necessity of remembering that all clinical tests have not been made, and still more positively points out that the remedy is of value in pulmonary phthisis only when the disease is in its earliest stages. No one who stops to think can believe otherwise, for regeneration of specialized tissues in man is practically never accomplished, and a lung once seriously involved or broken down cannot be replaced.

Without approval or condemnation it is proper for us to wait for more information, and at least to give Koch credit for a splendid attempt if not a glorious victory over disease.

The readers of THE MEDICAL NEWS can rest assured that they will be kept well informed of all matter pertaining to the subject that possesses official sanction, and that resort to full cable dispatches will be made, as in the issue of this journal for November 15th, should anything of particular interest be made public.

A LEGAL ERROR.

THE absolute inability of the ordinary jury to decide as to questions in which medical points are involved has, with unfortunate frequency, resulted in unjust verdicts and unfortunate convictions. Not only do juries reach verdicts which are as wonderful as they are wrong, but it is a notorious fact that even the judges seem to be unable to see the right side of a medical case and, in consequence, so charge the jury that there is little left for this body to do but to bring in the defendant as guilty.

Our attention is called to this subject particularly by an article which appears in the August and September numbers of *The Medical Standard*, of Chicago, detailing a case in which, for the purpose

of making a diagnosis, and also with the hope of affording relief to the patient, who was suffering from marked dyspnœa, a physician introduced an aspirating needle in the axillary line between the sixth and seventh ribs to the depth of one and one-half inches. Immediately after the operation there was some evidence of collapse, which was combated by the administration of brandy and other stimulants; but after this time the patient gradually grew worse and died on the fifth day. Before his death, however, a homœopath was called in, who ultimately made an autopsy, assisted by two others of his own school. Having no love for the regular physician who had previously been in attendance, it was not difficult for these gentlemen to make the friends believe that malpractice had been resorted to by their predecessor, and the result was a trial in which the jury promptly brought in a verdict of guilty against the defendant, notwithstanding the judge's charge to the contrary. On the second trial the verdict was given against the defendant once more with damages at $50, the judge in this instance directing the jury to bring in a verdict *against* the defendant, stating that "expert evidence is a lower order of evidence, and ought not to overthrow positive and direct evidence of witnesses who testify to facts in conflict with such experts." Such an expression of opinion upon the part of the judge is opposed to that of the decision of the Supreme Court of Iowa, which decided that the expert evidence of physicians as to the nature, diagnosis, and treatment of disease is the highest order of evidence. However, this statement of Judge Couch in this particular instance applies with considerable force to the testimony of the homœopaths, which had much to do with the conviction of the defendant. They both stated that it was never proper to use the aspirating needle for the purpose of aiding in making a diagnosis, and one of them testified that he had never heard of such a thing. Further than this, it was asserted by these followers of Hahnemann that the diaphragm is not attached to the inner walls of the chest, is of no particular use, and has no function to perform.

At this distance it is not possible for us to decide as to whether the regular physician inserted an aspirator in such a way as to injure the liver and lung, but that death should have occurred as long as five days after this operation seems to prove that this simple procedure could scarcely have caused a fatal result, even if carelessly performed. Further than this, the post-mortem showed ample cause for death in the presence of far advanced diseased processes.

CORRESPONDENCE.

CHICAGO.

To the Editor of The Medical News,

Sir: Since the foundation of St. Luke's Hospital, on February 17, 1864, until September 25, 1890, 9277 persons have been received and cared for as in-patients. During the last year 819 were admitted to the wards and rooms, and 2360 received medical advice and surgical treatment at the dispensary free of charge. While the hospital is free to those who cannot afford to pay, there are some rooms set aside for those who can afford to do so. Pay-patients can also be admitted to the wards. Of the 819 admitted in 1889 270 were pay or part-pay patients, the amount paid into the treasury by them being about $9000. The number of days of hospital care given during the last year was over 24,000—16,140 days, or 67 per cent., being given to charity patients. This makes the average stay of the 819 patients nearly one month. The average cost of each patient per day, aside from the cost of repairs, was $1.465. The admissions from the Episcopal Church were 77; from other Christian bodies 515, of whom 219 were Roman Catholics. The expenses for the year were $38,980.77.

The Woman's Physiological Institute has for its distinctive object a series of free afternoon lectures on the subjects of hygiene and sanitary science. All women are cordially invited to avail themselves of the opportunity to listen to able and instructive physicians and educators who have gratuitously contributed their time and talents to this enterprise. A course of twelve lectures is given. Dr. H. A. Johnson lectured before the Institute a few days since, his subject being "The Chest."

The overcrowded condition of the Cook County Insane Asylum will be relieved in a short time, when four cottages, now being erected, will be ready for occupancy. These cottages will accommodate 300 patients. The Asylum was badly crowded when Dr. Benson took charge, and he has done much to lessen the inconveniences which formerly existed.

Dr. James A. Lydston, in a paper on the "Etiology of Cataract," recently read before the Chicago Medical Society, advocated the theory that there is a relationship between the functions performed by the crystalline lens during accommodation and the formation of cataract, stating that he believed that the proper maintenance of accommodation depended upon the tonicity of the ciliary muscle, which is brought about by the process of osmosis taking place between the crystalline lens and the aqueous and vitreous humors; and that, if the tonicity of the ciliary muscle is impaired from any cause, degenerative changes will begin to assert themselves, and will be manifested by a more or less dense opacity of the lens.

Dr. Lydston further calls attention to the changes observed in the lens in advanced age, and believes that

the osmotic process, upon which the lens depends for nutrition, is favored by the periodical contraction and relaxation of the ciliary muscle during accommodation.

Dr. D. W. Graham reported to the Chicago Pathological Society a very unique case of a foreign body in the stomach of a child twenty-two months old. The child was believed to have swallowed some unknown object, but whether it was more than a piece of bread or other solid food was not known. The child slept, and ate and digested its food as usual, and there were no marked symptoms except crying-spells which were severe and frequent, as if from colic. When six weeks had elapsed a small abscess formed in the left hypochondriac region close to the costal cartilage, at a point corresponding to the mammary line. The abscess was opened, and, after several days, a foreign body was discovered in the wound. Dr. Graham now saw the case, and found what proved to be a lady's hat-pin projecting into the wound. The pin could be easily pulled out for several inches, but was arrested by the head, which was too large to pass through the opening. Dr. Graham now proceeded to do what probably proved to be the simplest and easiest laparotomy and gastrotomy on record. A grooved director was passed along the shaft of the pin, by the aid of which the opening was enlarged with a probe-pointed bistoury sufficiently to allow a pair of strong-jawed hæmostatic forceps to be pushed in where the probe had been. The object of this was to force the head from the shaft of the pin. This was soon accomplished, when the shaft was easily lifted out. Some gas escaped, and enough of liquid and partially-digested food to show that the track led directly into the stomach. The glass head was passed with the fæces on the following day, in two pieces. The shaft measured five and one-third inches in length. The wound healed at once, requiring only one re-dressing. No stitches were used to close the wound. The stomach was firmly adherent to the abdominal wall, which rendered the problem of the method of procedure and the operation very easy.

Among the cases of unusual interest lately presented to the orthopædic class at the Chicago Polyclinic, was one of spasmodic wry-neck successfully treated by spinal traction and incision of the urinary meatus.

Professor Charles F. Stillman, in remarking upon the case, alluded to the profound effect upon the nervous system produced by some malformations of the penis, and cited a number of instances of locomotor ataxia and other nervous diseases which had been somewhat improved by complete division of the meatus when contraction existed. The patient above referred to exhibited a penis in which the meatus was entirely closed by membrane, and after its removal the canal was found to be normal throughout its whole extent. The patient had previously urinated through a small sinus in the frænum. A congenital pouch existed at the extremity of the penis, retaining a few drops of urine.

The patient was thirty years of age, and had always been nervous and irritable, but had had no serious illness until September, 1889, when the head exhibited a tendency, without known cause, to turn toward the right, with the chin elevated, which condition gradually grew worse, and was soon complicated with tremor and spasm. When first seen, in April, 1890, he had spasmodic torticollis, and for several months previously had been confined to his room.

The treatment consisted of exercise, during traction upon the spinal column on both the upright and recumbent curved boards, together with the operation already referred to, and was attended with entire success. The case was considered of interest because of the well-known obstinacy of these cases to ordinary remedies.

Dr. George F. Fisk recently read an interesting paper on the "Use of the Phonograph in Testing the Hearing," before the Chicago Medical Society. His method of using the phonograph in his own practice is to prepare the cylinder in the absence of the patient, speaking fifteen or twenty test-words in a loud and even voice into the machine. Such words the phonograph reproduces so that a person of normal hearing can distinguish them at a distance of from twenty to forty feet, according to the strength of voice used in recording them. No hearing-tube is used, simply the air-conduction in a quiet room. The patient is at first placed thirty or forty feet distant from the phonograph—beyond hearing-distance—and then gradually brought to a point where most of the words can be correctly repeated. The words heard, hearing-distance, name of patient, date, etc., are then recorded on the same cylinder, which is given to the patient for use at another examination or in consultation with another aurist. It is believed that the phonograph is the only instrument to test the hearing which fulfils the following conditions: (1) It makes use of human speech; (2) it is accurate and independent of the examiner; and (3) it makes a record capable of interpretation and use by other aurists.

In examining several phonographs with the same cylinder, and controlling the hearing-distance by two observers possessing normal hearing, no difference could be detected in the different machines. At present five accurate copies have been made of a given cylinder, but at great expense. If indefinite reproduction from a given cylinder (phonogram) shall in the future become possible, then aurists in different parts of the world can use the same tests, and their records and tests will become perfectly intelligible to one another, as is the case now with the oculists' records through the universal employment of Snellen's test-types.

ST. PAUL AND MINNEAPOLIS.

To the Editor of THE MEDICAL NEWS,

SIR: Nothing of very great interest to our profession has lately occurred in Minnesota. We have had our annual meeting of the State Society, at which the following officers were elected:

President, W. L. Beebe, M.D.; First Vice-President, W. D. Flinn, M.D.; Second Vice-President, F. E. Bissel, M.D.; Third Vice-President, J. E. Moore, M.D.; Secretary, C. B. Witherle, M.D.; Treasurer, R. J. Hill, M.D. Some interesting papers were read and cases shown, and as a whole the meeting was a very successful one.

Perhaps of the most interest to the profession at large are the results of our excellent State Medical Law as shown by the report of the Secretary of the State Examing Board, Dr. Arthur Sweeney. This Examining Board has now been in existence for three years, and

although occasional difficulties have occurred in the administration of its duties, they have been of minor character and easily overcome.

Our first medical act was passed November 15, 1883. Under this act a State Medical Examining Board composed of the Regents of the University of Minnesota was organized. This board granted 1501 licenses, of which 1325 were granted to physicians with diplomas from recognized medical colleges upon registration of their diplomas; 33 to physicians after examination, and 143 (exemption certificates) to physicians who had practised in the State for five years prior to the passage of the act.

July 1, 1887, this act was repealed and the present act passed, on conviction that the act of 1883 was not an efficient barrier against incompetent practitioners. The following are some of the interesting features of the act:

The Governor of this State shall appoint a board of examiners, to be known as the State Board of Medical Examiners, consisting of nine members, who shall hold their office for three years after such appointment, and until their successors are appointed.

Provided, That the members thereof first appointed under this act shall be divided into three classes, each class to consist of three. The first class shall hold office under said appointment for the period of one year; the second class for two years, and the third class for three years, from the date of their appointment.

It is further provided that no member thereof shall be appointed to serve for more than two terms in succession, and no member of any college or university having a medical department shall be appointed to serve as member of said board, two of which shall be homœopathic physicians.

The Board of Medical Examiners shall hold meetings for examination at St. Paul, the capital of Minnesota, on the first Tuesday of January, April, July, and October of each year, and such other meetings as said board may from time to time appoint.

All persons hereafter commencing the practice of medicine and surgery, in any of its branches, in this State shall apply to said board for a license so to do, and such applicant, at the time and place designated by said board, or at the regular meeting of said board, shall submit to an examination in the following branches, to wit: Anatomy, Physiology, Chemistry, Histology, Materia Medica, Therapeutics, Preventive Medicine, Practice of Medicine, Surgery, Obstetrics, Diseases of Women and Children, Diseases of the Nervous System, Diseases of the Eye and Ear, Medical Jurisprudence, and such other branches as the board shall deem advisable, and present evidence of having attended three courses of lectures of at least six months each. The clause requiring "three courses of lectures of at least six months each" applies only to those who have been graduated later than July 1, 1887. When desired, said examination may be conducted in the presence of the dean of any medical school or the president of any medical society of this State. After examination, the board shall grant a license to such applicant to practise medicine and surgery in the State of Minnesota; which license can be granted only by the consent of not less than seven members of said board, and shall be signed by the president and secretary of said board, and attested by the seal thereof. The fee of such examination shall be the sum of ten dollars. The board may refuse or revoke a license for unprofessional, dishonorable or immoral conduct. In all cases of refusal or revocation the applicant may appeal to the appointing power of said board.

The examinations are conducted with the utmost fairness and justice. Each applicant writes his name opposite a number in a book, which number he places on his paper. It is against the rules of the board that the Secretary, who conducts the examinations, shall reveal the name of candidate until the latter has been granted or refused a license.

The examination lasts for two and a half days, two hours being allowed for each subject. The papers are forwarded in a sealed box to the examiner. After the close of the examination the full board meets, the markings are submitted to the secretary, and the candidates are then voted on by numbers, after which the results are announced.

The following rules and regulations govern the conduct of the examinations:

I. Any applicant for examination and license to practise medicine in this State, who is a graduate of *over five years'* standing before making application for such examination and license, shall be considered an "old practitioner," and any such applicant who is a graduate of *less than five years* shall be considered a "recent graduate."

II. Applicants who are "old practitioners" shall be required to obtain a minimum marking of not less than *sixty-five* per cent. in each of the following subjects: 1. Practice of Medicine; 2. Practice of Surgery; 3. Materia Medica; 4. Obstetrics, and Diseases of Women and Children; and a minimum marking of not less than *thirty-five* per cent. in each of the following subjects: 1. Anatomy; 2. Chemistry; 3. Physiology; 4. Pathology, Histology and Preventive Medicine; 5. Diseases of the Eye and Ear; 6. Medical Jurisprudence.

III. Applicants who are "recent graduates" shall be required to receive a minimum marking of *thirty-five* per cent. in: 1. Practice of Medicine; 2. Practice of Surgery; 3. Materia Medica; 4. Obstetrics, and Diseases of Women and Children; and a minimum marking of not less than *fifty* per cent. in each of the following: 1. Anatomy; 2. Chemistry; 3. Physiology; 4. Pathology, Histology, and Preventive Medicine; 5. Diseases of the Eye and Ear; 6. Medical Jurisprudence.

IV. No applicant shall be granted a license whose general average in all the subjects in which he is examined by this Board is less than *sixty-five* per cent., one hundred being the highest average possible for any applicant to obtain.

It will be noticed that the clause providing that to be eligible for examination, the applicant must present evidence of having attended at least three courses of lectures of six months each, excludes, as nearly as possible, applicants with an imperfect medical education. In spite of this clause, however, some of the answers to the questions are so ridiculous, and show such an utter lack of knowledge, as fully to impress anyone with the fact that some of our best schools sometimes send out very poor graduates. Dr. Sweeney, in his excellent *Register of Physicians*, states that since the passage of the act,

July 1, 1887, to July 5, 1890, "Thirteen examinations have been held, at which 205 candidates have presented themselves. Of this number 128, or 62.44 per cent., have been issued licenses, and 77, or 37.56 per cent., have been rejected. Of the total number of candidates, 62 had graduated five years prior to the date of examination, of whom 30 were licensed and 32 rejected. Two licenses granted by the former board have been revoked, it having been ascertained that the diplomas upon which the licenses were issued were fraudulent. One license has been revoked for unprofessional conduct in attending a patient while under the influence of intoxicants."

Under the old board of 1883 and the present one up to July 5, 1890, 1629 licenses have been issued.[1] On July 5, 1890, there were in active practice in the State 1191 physicians of all classes holding licenses, as follows:

Located.	Licensed on presentation of diplomas.	Exemption certificates.	Licensed on examination by the Board of 1883.	Licensed on examination by the Board of 1887	Affidavits of exemption filed.	Exempt by practice prior to 1887.

Total	848	156	38	149	1191

As the members of the Examining Board are chosen from the ranks of the profession not connected with any of the medical colleges, there is no chance of partiality in this direction. The board is a mixed body, composed of regular practitioners and homœopaths, the regulars being in the majority. Naturally some of the questions asked by men who are not teachers are sometimes peculiar, and some complaints are heard. As a whole, the results of the board's work have been eminently satisfactory to both applicants and the profession at large, and I think we can now say truly that Minnesota receives into the ranks of its medical profession only the better educated graduates from our best medical colleges.

[1] This table and the facts of this paper have all been taken from the Register of Physicians, issued by the Secretary of the State Medical Examining Board, Dr. Arthur Sweeney.

NEW YORK.

To the Editor of THE MEDICAL NEWS,

SIR: I have to chronicle an event of the greatest importance to the medical profession of this city, and one which it is confidently hoped will mark a new era in its history. I refer to the formal opening of the new building of the New York Academy of Medicine. Of course, there have been some grumblers, who, steeped in utilitarian ideas, could see no justification for this lavish expenditure for the new building, when, as they said, even on occasions of great interest, it was easy to find seats in the assembly hall of the old building. It is, unfortunately, true that the attendance at the meetings was often shamefully meagre, but the library had outgrown its bounds, and, more important than all this, those who had devoted much time and consideration to the advancement of the interests of the Academy, foresaw, with commendable wordly wisdom, that if the Academy desired to exert still more influence in public matters, it must place itself before the eyes of the public in a fitting position of dignity and honor; in short, it must show a proper self-respect if it would win the respect and esteem of others. This point was emphasized in the anniversary oration delivered by Dr. E. L. Keyes, when he said that if there were sermons in stones, then the very walls of the building had already delivered an address in a strain of far greater dignity than any to which he could aspire.

The new home of the Academy, which is at No. 17 West Forty-third Street, near Fifth Avenue, is a very accessible location, and is as nearly central as it was possible to obtain. Compared with the accommodations of this medical body in a room over a coal-yard, forty years ago, this new edifice is superb. It covers a plot, 75 x 100 feet, and has a basement, four full stories and two half stories. The front is partly of fine red sandstone and partly of brick, the apex of the gable being finished in carved stone-work. The main assembly hall with the adjoining banqueting hall is a memorial of the late Dr. Alexander Hosack, and is known as Hosack Hall. The smoking-room adjoins the assembly hall, and, by opening the dining-room and this smoking-room, one large hall can readily be obtained when needed for unusually large gatherings. Such an arrangement was particularly valuable on the evening of its formal opening, for upward of one thousand ladies and gentlemen assembled to do honor to the occasion. The second story is mainly occupied by the reading-room and library, with its abundant accommodations for the current medical periodicals, and a book-room capable of holding two hundred and fifty thousand volumes. The third and fourth stories contain small meeting-rooms for the Sections of the Academy, and for other societies; also rooms for laboratory work; and one provided with a skylight, so that Fellows who have not sufficient light in their offices may be able to photograph their cases. The building is finished in a beautifully fine and very dark antique oak; ventilation is secured by a revolving fan in the basement; and the illumination is by incandescent electric lights arranged on very tasteful fixtures.

The opening exercises, to which I have alluded, were held on the evening of November 20th. After the invocation by the Rev. Dr. Howard Crosby, Dr. Alfred L.

Loomis delivered the President's address, in which he spoke of the eminent men who founded the Academy, of its proud record for scientific work, and of its library of forty thousand volumes, together with the largest and best collection of journals to be found in the country. He said that, as there were well-organized sections in all the special departments of medicine and surgery, each Fellow might find a congenial place in which to work. They were under no obligations to the past, but under bonds to the future. The career of the physician of the future would be nobler and pleasanter, because he would have less of ignorance and prejudice to combat, but he would require a higher culture than his representative of to-day. In closing his address, he said: "So shall the congratulations, which we utter to-night, re-echo from these walls when other voices recall this day. Join with me, then, in thanksgiving to the Great Physician for what has been accomplished, and in this invocation, that those walls may not crumble or cease to shelter faithful, earnest, Christian men, until suffering humanity is free from its bondage to lust and excess, and is victorious in its struggle against the invisible arrows of disease." In the course of his oration, Dr. Keyes said that, "although the idea of founding such an Academy of Medicine was conceived and began to take shape in the latter part of 1846, it was not until December 12, 1874, that it secured a home of its own at 12 West Thirty-first Street. One of its important functions had always been the promotion of the public health, and how truly it had done its part in this direction was to be seen in the "existence of our efficient city Board of Health, which was conceived and formed in the bosom of this Academy in the interest of the citizens of New York." The membership of the Academy had reached nearly seven hundred, and the library, which was among the youngest, having been founded by donations in 1877, was already safely housed in a fire-proof home, and occupied the third place numerically in the medical libraries of America, and the fourth place among the purely medical libraries of the world. It was but natural that much should be said on this occasion in praise of the library, of which all New York physicians are justly proud, and, it is safe to say that that feeling was greatly enhanced by the description given by Dr. S. Weir Mitchell, of the miserable way in which the library of the French Academy was housed. When Dr. Mitchell asked why it was so poorly classified and arranged, he was told that they were "waiting for the Government to put up a new building." Surgeon-General John S. Billings, in offering congratulations on behalf of the medical officers of the army and other departments of the government, said that the central feature of this Academy was its library, and facetiously added that he would like to say a few things about the "*branch* of this library in Washington." At that "branch," they are always ready to extend such courtesies to the profession as is possible, but their work in this direction had been somewhat misunderstood. About one year ago, the editor of a leading medical journal of New York City suggested to a correspondent, asking for a certain kind of information, that he might obtain it for a small compensation by applying to the Surgeon-General at Washington. Dr. Billings said that he then had a very realizing sense of the great power of the press, for he was immediately overwhelmed with all sorts of letters and inquiries. Dr. Reginald Fitz, of Boston, spoke of the principal library in that city, and Dr. Abraham Jacobi pictured the needs of "our library," and made an eloquent plea for financial aid for it. The venerable Fordyce Barker, who was introduced as one "whose Presidency marked a new era in the history of the Academy," was received with enthusiastic applause. In a few well-chosen words he offered his congratulations, and said that that auspicious occasion would have been long delayed had it not been for the zealous work of the President and of his immediate predecessor, Dr. Jacobi. Dr. S. Weir Mitchell, in offering the congratulations of the College of Physicians of Philadelphia, took the opportunity of calling the attention of the general public to the fact that what we are often pleased to style "our profession," is rather a guild or brotherhood, possessing a creed of morals including honor, chastity, brotherhood, and the largest charity; the records of much of its work not being kept in the books of this world. As regards the charity of the profession, he thought the public generally did not understand that two-thirds of the most celebrated physicians of New York City gave three or four hours a week to free work among the poor. He was not aware that a similar custom existed among merchants or lawyers.

At the conclusion of the speeches, a collation was served in the banqueting-room. Letters of congratulations were read from well-known physicians in Chicago, New Haven, Boston, and elsewhere, and Oliver Wendell Holmes sent a characteristic letter, which was a fitting close to this memorable occasion. He said: "Academies have been too often thought of as places of honorable retirement and dignified ease: roosts where emeritus professors and effete men of letters, once cocks of the walk, could sit in quiet rows, while the fighting, the clucking, and the crowing were going on beneath them. But the academy which fulfils its true function is a working body. We look to this great and able body of men to guard the sacred avenues to the temple of science against all worshippers of idols. The medical profession will always have to fight against the class of wrong-headed and dishonest individuals and schools, as they call themselves. There are a certain number of squinting brains as there are squinting eyes among every thousand of any population, and there will always be a corresponding number of persons, calling themselves physicians, ready to make a living out of them. Long may it be before the wholesome barriers are weakened that separate the thoroughbred and truly scientific practitioner from the plausible pretender. I trust it will always be enough for a physician to be able to say, 'I am a member of the New York Academy of Medicine.'"

MILWAUKEE.

To the Editor of THE MEDICAL NEWS,

SIR: In the busy and generally uneventful round of professional life as it here exists, your chronicler for Milwaukee and vicinity finds comparatively little that is of interest regarding medical affairs. The subject at present uppermost in the professional mind here, as elsewhere, is the new remedy for tuberculosis. The

leading men of the profession look upon the subject encouragingly, and hope that Koch may, in these latest investigations, add to his already brilliant reputation and furnish to the world an effective weapon against the "great white plague." Dr. H. M. Brown, of Milwaukee, left for Berlin on November 22d to study the subjcet in Koch's laboratory. Dr. Conway, of Chicago, has also gone, at the request of Professor Ingals, for the same purpose. Drs. Frank and McDill, of this city, are already spending the winter in Berlin, and will undoubtedly avail themselves of the opportunity to study and investigate the subject.

Apropos of the subject of laboratory work, the need of a good working bacteriologist and laboratory in Milwaukee often finds expression. The average general practitioner is not usually a man fitted for the work either by inclination or previous training; and the time, to speak of one item only, required for satisfactory work is so great that the man in general practice can accomplish little or nothing in bacteriology. It is hoped that a fund contributed by wealthy citizens and controlled as might be deemed wise by some local or State society, may place at our disposal a well-equipped laboratory under the direction of a skilled pathologist. At present morbid specimens are not infrequently sent to Washington, New York, or Philadelphia for examination. The private laboratory of Mr. Edward Allis, in this city, is an example of what can be done in the manner suggested above. The work done is purely biological and is under the superintendence of Professor E. O. Whitman. Issued quarterly from this institution and edited by the gentlemen named, is the *Journal of Morphology*, the scope of which is defined in its title, and its high scientific standing is attested by the favorable notices it has received from the highest authorities in biological science both in this country and in Europe.

During the late summer and fall typhoid fever has been more than usually prevalent, and more recently an unusual increase in the number of cases and deaths from diphtheria has been noticed. In one section of the city it was deemed advisable to close for a short time one of the public schools, and other special precautions have been taken by our Health Commissioner, Dr. Wingate, to limit the spread of the disease. Notwithstanding these facts Milwaukee still maintains its reputation as a healthy city, its death-rate per thousand being less than that of other neighboring cities of about the same or larger size.

The Emergency Hospital recently extended its field of usefulness by the addition of a maternity ward. It is hoped that this institution, which has already demonstrated its worth, may in the near future find a better habitation; for a new building and a larger equipment are needed.

The State Medical Society has just published its transactions for the current year. This is the twenty-fourth volume of proceedings and compares favorably with previous issues; the papers and discussions which it contains indicate a growing interest in the work of the society on the part of the physicians throughout the State. The society is still at work on the subject of State medical legislation, and the matter will probably again be brought up at the next meeting of the State Legislature. The meeting of the State Society for next year will be held at Madison. The officers of the society are: Dr. George D. Ladd, president; Drs. F. E. Walbridge and B. T. Phillips, vice-presidents; Dr. J. R. McDill, secretary.

ST. LOUIS.

To the Editor of THE MEDICAL NEWS.

SIR: Our medical societies are now holding their regular weekly meetings again. At the St. Louis Medical, which meets in the hall of the public school board every Saturday evening, one or more papers are read and cases are reported more or less formally.

The subject of pyosalpinx has been attracting a good deal of attention in the societies for several weeks past, some very interesting specimens having been exhibited and the cases reported and discussed.

The Medico-Chirurgical Society is also holding its meetings every week instead of bi-weekly, as formerly, and the new society hall and reading-room are very convenient and pleasant. The question of lengthening the term of study preliminary to graduation from medical schools has attracted a good deal of attention here this fall, and the discussion has resulted in interviews of different professors of medical colleges by reporters of the daily newspapers. The Missouri School of Medicine (Medical Department No. 2, of the Missouri State University) has announced that after the current year a three years' carefully-graded course of study will be required of all applicants for graduation at that institution. The St. Louis school has enforced this rule for several years, beginning at a time when scarcely any of the Eastern colleges made that requirement.

The other three schools have not yet been able to adopt a three years' course.

A few days ago, after reading in one of the journals an obituary notice of Dr. Montrose A. Pallin, I chanced to pass the building which was his home when he lived here, and noticed upon it a sign with the words "The Montrose." In the rapid westward growth of our city the change from the fashionable residence to the boarding-house is the common fate of many handsome buildings; but I do not remember another instance of the utilization of the name of a former owner to increase the popularity of a boarding-house.

There has been an unusually large amount of continued and typhoid fevers this fall instead of the ordinary intermittent malarial fevers which we expect at this season of the year. In one case which occurred under my observation a girl of sixteen years had a temperature of 106.8° on five successive days in the fourth week of a fever which continued six weeks before convalescence occurred.

The St. Louis Training School for Nurses graduated a class of seven a few weeks ago. The women who are carrying on this school have done an excellent work, and the graduates of the school, having had a two years' course of study and training, are admirably qualified for their work.

NEWS ITEMS.

VARIOUS cablegrams from Berlin all agree in supporting the opinion expressed in the editorial in this number of THE MEDICAL NEWS concerning the useless-

ness of either doctors or patients travelling to Berlin at this time with the idea of obtaining any of the benefits which may accrue from the employment of Koch's antitubercular fluid.

Various regimental surgeons in different portions of the German army have been ordered to set aside soldiers under their care who are suffering from tuberculosis, in order that the service may be benefited as early as possible, but it is worthy of note that nearly ninety per cent. of the cases which are receiving injections of the antitubercular fluid are not sufferers from pulmonary tuberculosis, but chiefly from lupus and allied diseased conditions.

We are also informed through the cable that there are already hundreds of English doctors in Berlin who are permitted to see little and who have opportunity to learn less. They all agree in complaining bitterly of the scant courtesy which is shown them, and it is asserted by those who ought to know that the same treatment will be shown to the American doctors when they arrive.

Professor Koch has always been notorious for the seclusion which he insists upon, and to see him now is absolutely impossible. He has also practically limited the employment of his liquid to von Bergmann, Cornet, and Levy, all of whom in one way or another have placed the discoverer under personal obligations by favors done him in the past. So complete a monopoly have these men of the employment of the liquid that they have established numerous private hospitals in Berlin, in which they charge exorbitant prices, both for living expenses and medical attendance. Thus it is said that Levy charges every patient $25 for each visit, and that even with this extortionate price he treats nearly two hundred patients daily. The other physicians, it seems, are not far behind Levy in their charges, and physicians, students, and patients are endeavoring by every means in their power to obtain information which cannot be had. The number of consumptives who have flocked to Berlin from all parts of the Continent reaches several thousand, and it is supposed that at least 1700 of these have already been treated—none of them, of course, as yet with marked improvement in their condition. The fact that so many consumptives have applied for relief is said to be a source of much distress to Dr. Koch, who realizes better than anyone else apparently that his remedy is not a cure-all.

A Hospital at Long Branch, New Jersey.—The rapidly-growing town of Long Branch, New Jersey, has for several years felt the need of an infirmary. This want has been met by the purchase, by the Monmouth Memorial Association, of a large hotel property, which can easily be converted into a well-appointed hospital. Dr. S. H. Hunt, President of the Association, has been chiefly instrumental in carrying the project through.

Physicians at Law.—Dr. Marcely, of Buffalo, N. Y., is suing Dr. Tremaine, of the same city, for $25,000 damages for libel. It is stated that Dr. Tremaine referred to Dr. Marcely in a Society meeting as a "notorious quack," and asserted that electrical treatment as an alleged radical cure for hernia was quackish practice. Both are regularly educated physicians, Dr. Tremaine being Emeritus Professor of Surgery in one of the medical schools of Buffalo.

Case of Aconite-poisoning.—A correspondent reports a case of aconite poisoning in a farmer in Nebraska, who, having obtained some tincture of aconite for the purpose of using it as a liniment upon his horse, made an application of the liquid to his own head in order to relieve a headache. He rapidly developed symptoms of aconite-poisoning, and died in about twenty-four hours.

Alvarenga Prize.—The College of Physicians of Philadelphia announces that the next award of the Alvarenga Prize, being the income for one year of the bequest of the late Senor Alvarenga, and amounting to about $180, will be made on July 14, 1891. Essays intended for competition may be upon any subject in medicine, and must be received by the Secretary of the College, Dr. Charles W. Dulles, on or before May 1, 1891.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM NOVEMBER 18 TO NOVEMBER 24, 1890.

Moseley, Edward B., *Captain and Assistant Surgeon.*—Is granted leave of absence for one month.—*S. O. 100, Department of Texas*, November 17, 1890.

By direction of the Acting Secretary of War, leave of absence for six months, on surgeon's certificate of disability, with permission to go beyond sea, is granted Henry G. Burton, *Captain and Assistant Surgeon.*—Par. 9, *S. O. 269, Headquarters of the Army, A. G. O.*, November 17, 1890.

By direction of the Acting Secretary of War, John L. Phillips, *Captain and Assistant Surgeon*, is relieved from further duty at Fort Crawford, Colorado, to take effect on his relinquishing the unexpired portion of his present leave of absence, and will report in person to the commanding officer Camp Guthrie, Oklahama Territory, for duty at that station reporting by letter to the commanding general Department of the Missouri.—Par. 7, *S. O. 269, A. G. O., Washington*, November 17, 1890.

By direction of the Acting Secretary of War, leave of absence from January 1, to March 24, 1891, inclusive, with permission to go beyond sea, is granted Henry Johnson. *Captain and Medical Storekeeper.*—Par. 18, *S. O. 268, A. G. O., Washington*, November 15, 1890.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING NOVEMBER 22, 1890.

Ayers, J. G., *Surgeon*.—Ordered to the U. S. Receiving-ship "Wabash."

Evans, Sheldon Guthrie.—Commissioned an Assistant Surgeon in the U. S. Navy.

Bates, N. L., *Medical Director.*—Ordered as President of the Naval Medical Examining Board at Mare Island, Cal.

Moore, A. M., *Surgeon.*—Ordered as a member of the Naval Medical Examining Board at Mare Island, Cal.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FROM OCTOBER 26 TO NOVEMBER 15, 1890.

Carter, H. R., *Passed Assistant Surgeon.*—Granted leave of absence for fifteen days, November 14, 1890.

Guiteras, G. M., *Assistant Surgeon.*—Granted leave of absence for thirty days, October 29, 1890.

Hussey, S. H., *Assistant Surgeon.*—To proceed to the South Atlantic Quarantine Station for temporary duty, October 28, 1890.

Geddings, H. D., *Assistant Surgeon.*—Granted leave of absence for fourteen days, November 14, 1890.

Groenevelt, J. F., *Assistant Surgeon.*—To report to the Superintendent of Immigration for temporary duty, October 28, 1890.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LVII. SATURDAY, DECEMBER 6, 1890. NO. 23.

ORIGINAL LECTURES.

ONE YEAR'S WORK IN DISEASES OF THE RECTUM AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

BY CHARLES B. KELSEY, M.D.,

PROFESSOR OF DISEASES OF THE RECTUM.

GENTLEMEN: At the close of this, the first year of clinical instruction in diseases of the rectum, it is interesting to glance back over the case-book and see what has been accomplished. If the amount of material has not been as large as it doubtless will be in the future, it is because sufficient time has not yet elapsed to make this new departure in hospital work known to the sufferers who are benefited by it. And yet those of you who have been with me any length of time have had a chance to see almost all diseases of the rectum and the operations for their relief.

We have had 125 patients, showing 131 cases of disease of the rectum. These in the order of their frequency are as follows:

Hæmorrhoids	42	Deep pelvic abscess	3
Fistula	15	Congenital malformations	3
Fissure	12	Polypus	2
Benign stricture	9	Recto-vaginal fistula	2
Ulceration	6	Recto-vesical fistula	2
Pruritus	6	Paralysis of rectum from spinal disease	2
Superficial abscess	5	Urethral fistula and abscess	1
Cancer	5	Foreign body	1
Prolapse	4		
Papilloma	4		

For these various affections 67 operations have been done before the class, as follows:

Hæmorrhoids	17	Excision of rectum	3
Fistula	12	Polypus	2
Fissure	8	Plastic operation on anus	2
Colotomy	6	Recto-vaginal fistula	1
Abscess (superficial	4	Deep pelvic abscess	1
Prolapse	3	Proctotomy	1
Ulcers	3	Foreign body	1
Papilloma	3		

You will observe at once that the number of severe and unusual cases (cancer, benign stricture, congenital malformations, etc.) is out of all proportion to the whole number of cases seen, probably because our medical friends are kindly sending us these cases, while the simpler ones take care of themselves. As a natural consequence our death-rate has been high—3 cases in 125—much higher than will be met in practice, as cases generally run. Without the least desire to explain away this rate of mortality or make it appear less than it is, it is instructive to call attention to it more fully. In one case we did an inguinal colotomy on a man at the point of death, regardless of statistics, but in the desperate hope of prolonging his life. You remember the case of the man whose stricture was divided by a deep posterior incision three months ago. Contrary to my usual practice, the incision was not continued outward through all the soft parts about the anus for drainage, but a drainage-tube was carried backward from the stricture through the skin at the tip of the coccyx. This procedure has served me well in other cases, and saves much time in the healing of the cut, but I advise you against it. The drainage is by no means as perfect as when the anus is divided, and a fistula may remain in the track of the tube. I do not know that the character of the drainage had any effect in this particular case, but on the third day an immense phlegmon appeared on the left side of the anus and in the perineum—a true septic periproctitis. Free incisions were at once made and constant antiseptic irrigation kept up, while for many days large sloughs of cellular tissue worked their way out through the cut. The patient went very near to death's door at that time, but rallied after a fortnight, and seemed on the point of recovering, when a diarrhœa began which never ceased. Six weeks before his death we tried to put the abscess in a condition to heal, and discovered, under ether, the frightful destruction it had caused. The superficial openings were turned into one, the cavity was cleared of its unhealthy granulations, but the finger passed into the ischio-rectal fossa and up into the pelvis parallel with the gut, and no limit to the suppurating cavity could be reached. There was a large opening between the rectum and the abscess just within the anus, and another higher than the finger could reach, which allowed all of the fæces to escape from the rectum into the abscess cavity. The attempt to excite reparative action failed, the abscess steadily extended into the pelvis, and as was shown by frequent hæmorrhages, vessels were opened up, and, finally, a few days before death, a communication was made with the bladder. At first the flow was entirely from the bladder into the abscess, but twenty-four hours before death signs of acute cystitis began to show themselves, and for this, as a last resort, colotomy was done. Those of you who saw the operation remember with what extreme rapidity it was performed (seven minutes from the first incision to the dressing), and how little shock attended it. The patient rallied well and seemed none the worse, but later on sank quietly and died the same evening. You can therefore judge as well as I of the influence of the incision upon the result.

In another of the fatal cases following colotomy the influence of the operation was, I think, absolutely *nil*. The woman had a cancerous stricture of the rectum, with secondary deposits throughout the abdomen in the mesentery and omentum. As it was impossible for her to relieve the bowels, the left inguinal operation was done, and we had great difficulty in finding any coil

of gut, small or large, sufficiently free from cancerous adhesions to permit its being drawn to the surface. The sigmoid flexure was, however, finally attached to the wound and the dressing applied without incising the gut. Forty-eight hours after the operation the patient suddenly developed all the signs of severe illness—chill, high temperature, and immediate collapse. Thinking that the acute obstruction at the site of the incision might be the explanation of the condition, I hastened to open the gut, but the intestine was not at all distended, and no gas escaped, as is usually the case. It being manifest that no obstruction existed at the point of operation, the case was supposed to be one of septic peritonitis, and the collapse and general cancerous infection decided us against further surgical interference. At the autopsy it was found that the patient died of acute intestinal obstruction, which was, however, entirely unconnected with the operation and in no way due to it. At the splenic flexure of the colon, many inches above the wound, the gut was tightly bound down and sharply flexed by a cancerous mass in the mesentery, and against this point a lump of solid fæcal matter had impinged and completely obstructed the lumen. In her feeble condition the fatal result followed in a few hours.

The third death was no less interesting and instructive. In this case we excised a cancerous rectum, the disease reaching high up, but not beyond the limit of digital examination. Excepting the presence of chronic intestinal obstruction the patient was in good condition and the case a favorable one for operation. After the disease had been removed a complication occurred which I was unable to explain at the time, but which became very evident at the autopsy on the following day in the dilated sigmoid flexure. A large mass of fæces, in fact an impaction as large as a child's head, was found, which I removed, piece by piece with the fingers before suturing the ends of the gut. No force was used, and yet before all had been removed there was free hæmorrhage, not from the wound, but from the inside of the upper end of the gut. After all of the collection had been scooped out the bleeding still continued, and after suturing the divided ends and putting in the drainage-tubes, it was necessary to apply a tampon of charpie within the bowel in order to check the flow of blood. As the ether passed off the patient began to complain of most violent abdominal pain, and after twelve hours, during which no relief could be given him, he died in collapse. At the autopsy a rent was found in the upper part of the rectum, but not connected with the wound, through which fæcal extravasation had taken place. The rent was in the middle of a part of the gut which had become as thin as blotting-paper from the ulceration, caused by the direct pressure of the fæcal mass.

Of the three deaths, then, it seems but fair to say that though they all followed within a few hours of capital operations, two were in no way due to the operation, and the third was not prevented by it.

In our other four colotomies we have had good results, both immediate and remote, as a result of this procedure. Two of the cases you have seen to-day, namely, the doctor with the non-malignant ulceration and stricture high in the bowel, which was incurable by any other method of treatment, and the little child of seven months born with an imperforate anus. This case I should not have been surprised to see die after the operation, so weak and marasmic was he, and so great was the distention of the abdomen. You remember how, when the incision was made, nearly the entire intestinal tube came out through the wound, the large gut distended to about the size of two thumbs and the small one shrivelled and contracted. The child was born with no anus at all, and at the time of birth a deep incision was made which reached the blind rectal pouch. As is always the case, the little patient had with difficulty been kept alive for seven months, suffering about equally from obstruction and the efforts made by bougies to overcome it. At the time of the colotomy it had gone several days without any passage, and then had unloaded the gut by five or six fluid stools, due to one of those violent intestinal convulsions by which nature so often overcomes for the time a chronic obstruction. These are not favorable conditions for the operation of colotomy, and yet the child has done well; nor, should it live, need it be so great an object of sympathy, for if adults in the higher walks of life are contented in this condition and grateful for the relief afforded, surely it may be borne by one who has never known a different condition.

We have been especially fortunate in the number of cases of this sort of congenital malformation brought to the clinic in the year. Many men in active practice have never seen a single case, and yet we have had three. Both of the others were simple fibrous partitions between the rectum and anus, which allowed the escape of a small amount of fæces, and might have been relieved, at least for a time, by division and subsequent dilatation, had the parents consented; but this case was of a more serious character, and left us no hope of prolonging life for any great length of time except by more radical measures.

I show you the case again to-day, one week after the operation, and the difference in the child's general appearance is very marked. You would hardly believe that it has reached the age of seven months, so small and marasmic is it; but the vomiting, restlessness, and fretful crying have ceased, and the little patient is dividing its time between eating and sleeping. I have been asked, rather sarcastically, whether it was not possible to relieve the obstruction in this case without cutting the baby open, and for answer I point to the child. One gentleman has introduced his finger into the cicatricial tissue which forms the anus, and at about an inch from the surface feels an obstruction which he rightly believes could be cut through. There is no doubt about this; but, after cutting, the stricture must be kept open by dilatation, and the results of seven months of this treatment are shown in the present condition of the baby. Does a few months more of the same treatment bid fair to restore the child to health? In this matter we have been guided not only by the manifest dying condition of the child, but by the recorded experience of such men as Brodie, Benjamin Bell, Velpeau, and Van Buren, each of whom has recorded his experience that the struggle is always a hopeless one, and after a few years ends fatally for the patient. Had I desired to give only temporary relief to the obstruction I should have cut and dilated the stricture; but wishing to see this child grow to adult age, I have made an entirely new outlet

for the fæces; and preferring to do this with the least possible shock and immediate risk, have made that outlet in the left inguinal region.

I want to call your attention to the differences in appearances between this anus and the one in the adult patient just seen. Here you see the wire suture which was passed through the abdominal wall and mesentery, and by which the gut was raised and held almost entirely outside of the abdominal cavity and bent on itself at an acute angle, still in position. We will remove it. You see also that the edges of the opening in the gut have been cut away so that you are looking directly into the interior of the gut. In the other case the gut was not drawn out of the abdomen to such an extent and none of its wall was sacrificed. This has been done with an object. The adult is suffering from benign stricture and ulceration at about five inches from the anus, which has rendered life miserable for nine years, and is incurable by any sort of local or general treatment save colotomy. But after this operation the ulceration is very likely to heal, and being a physician the patient may at first use bougies, either through the natural or artificial anus, and come back after a year or more to have the artificial opening closed. The opening has been made with the especial object of being able to close it in the future by a plastic operation, and without resection and suture.

In the baby there is no such hope, and the anus has been made so as completely to occlude the gut, leaving only a small opening into the distal portion to introduce the tip of a syringe for the purpose of washing out what fæcal matter may have been in the rectum at the time of operation.

Perhaps the most interesting, and certainly the rarest, case shown you was the girl of thirteen, with well-developed and advanced lupus of the ano-vulvar region and consequent stricture of the rectum, sent to us by Dr. Lee, of Newark. As far as I am acquainted with the scanty literature of this affection it is the only case on record in a child, and in this one it had existed since the age of seven years. Although the history is imperfect and the parents deny syphilis, it would seem that this case must have had a specific origin from the great improvement which has taken place after eight months' treatment by Dr. Lee with anti-syphilitic remedies. The child was shown again a few days ago and the ulceration had certainly been greatly diminished in extent, while the induration so strongly resembling elephantiasis which is characteristic of the disease had in great measure disappeared. The case when first seen seemed only suitable for colotomy, while now it appears in a fair way to recover.

Of benign strictures you have seen almost every variety, and likewise almost every mode of treatment. The congenital forms have been referred to. We have also had syphilitic stricture, stricture in a man associated with the practice of unnatural vice, that due to pressure of pelvic exudation in a woman, and that caused by simple ulceration neither lupoid, dysenteric, or tubercular—ulceration impossible to account for except by some such simple traumatism as may be caused by the lodgement of scybalous masses of fæces, or by childbirth. I have again and again called your attention to the small proportion of cases in which it was possible to discover any venereal origin of the disease, and have tried to impress upon you the danger of jumping to the conclusion that a stricture must of necessity be either cancerous or syphilitic.

In the way of treatment you have seen colotomy for the bad cases, excision where it was applicable, and simple proctotomy. What you have not seen are the results which may follow this last measure, when patiently and intelligently carried out, and supplemented by systematic dilatation in a better class of cases than are seen here. This is the one method which should be relied upon in a large number of cases, and by it many patients may be made comfortable for life; but, unfortunately, it is seldom applicable to the poor in hospital practice. It is a method for the rich, and one covering years of patient work; but by it I have seen the nearest approach to a cure of the disease. Proctotomy is only the beginning of the treatment, and you have seen that done here. But the patient has not returned to us, and we know that by this time she is preparing to go to some other hospital for something else.

In the treatment of hæmorrhoids the clamp and cautery operation has been used in all cases except one, and the question of its advantages has been left entirely to the decision of the class. You know what is claimed for it here—quicker recovery and less pain than by any other method of cure. You have seen the patients again and again able to come down stairs to the out-patient room forty-eight hours after the operation, and heard them say that after the first few hours there was only a sense of soreness and some pain on defæcation. You have seen physicians leave the hospital and start in comfort on long journeys on the fourth day, though you have never heard me advise such a procedure. Usually the patients stay in the house for one week; seldom do they wish to stay longer. Almost invariably they are able to urinate without the use of the catheter. Accidents have not occurred, and it has been impressed upon you that the surest way to avoid them is to cauterize thoroughly the stump held in the clamp after cutting off the body of the hæmorrhoid with the scissors; and to see that there is no bleeding from the cauterized surface. After the operation is finished, a large speculum is introduced, and the rectum well irrigated with bichloride solution. If there is no bleeding then, there is no more likelihood of secondary hæmorrhage than there is after the ligature; and if there is bleeding (not from the cutaneous cuts with the scissors, but from the cavity of the gut), the operation is simply not finished, and the bleeding point must be secured. The cutaneous bleeding is controlled by direct pressure with pad and bandage, as in the ligature operation.

Carbolic acid injections have been used in one case where this method seemed specially indicated. The woman was at the end of the third month of pregnancy and was covered with a syphilitic eruption, and operation was therefore out of the question; but she was suffering greatly and bleeding profusely with each act of defæcation. A few drops of a ten-per-cent. solution of carbolic acid were injected into two of the hæmorrhoids, and a third one, with an eroded strawberry-like surface, was painted with nitric acid, and all of the bad symptoms ceased. But I explained to you that the woman was certainly not cured, as she supposed herself, and that what was done was not free from serious risks of

sloughing and abscess, though less likely than a radical operation to produce a miscarriage.

The same thing may be done in many cases with the same happy results. It is a fascinating procedure to both patient and surgeon till the bad case comes along; but after causing one severe phlegmonous inflammation of the peri-rectal cellular tissue the *surgeon* generally abandons it for methods attended by less risk and by permanent results.

Of fistulæ we have had all varieties from the simpler ones which were cut in the out-patient room without ether, to those extending deep into the pelvis, and the case of combined recto-vaginal and vesico-vaginal openings, due probably to chancroidal ulceration. In the one case of large recto-vaginal fistula associated with an abscess behind the uterus, in which the attempt was made to reach and suture the opening by a Kraske's incision, the operation was a failure, due, perhaps, to the difficulty in getting at an opening so near the body of the uterus, or perhaps to the presence of the abscess discharging into the vagina at the site of the fistula.

Another bad case of fistula-in-ano, extending deep into the pelvis, was the one due to carious bone on the anterior and lateral surfaces of the sacrum. The first operation here also was a failure, because the incisions, though deep, were not deep enough. At the second trial the coccyx and lower sacral vertebræ were removed, the incision was carried along the side of the sacrum to about its middle, and the diseased bone scraped away. Tracks were then found running around the deep urethra on both sides behind the triangular ligament, which were also scraped out with the finger. The patient still reports to us occasionally with the wound entirely healed except a small sinus just admitting a probe, which leads to the stump of the sacrum.

ORIGINAL ARTICLES.

THE TREATMENT OF ENTERIC FEVER, WITH SPECIAL REFERENCE TO THE METHOD OF BRAND.[1]

By J. C. WILSON, M.D.,

PHYSICIAN TO THE HOSPITAL OF THE JEFFERSON MEDICAL COLLEGE AND TO THE GERMAN HOSPITAL, PHILADELPHIA.

A French medical writer has said, "When I see a young man die from typhoid fever, I experience the sensation of having witnessed a homicide." Here, as always, something of the truth is sacrificed to the desire to be epigrammatic, but no one who has carefully studied the subject, can fail to enter into the spirit which suggested this forcible statement.

In the first place, enteric fever, in theory at least, is a preventable disease. Our knowledge of its causation is to-day sufficiently extended and accurate to make it a preventable disease in practice. That it is not prevented in communities where it is endemic is largely due to the absence of positive convictions as to the material nature of the infecting principle and the possibility of destroying it or preventing its spread. It is the highest duty of the doctor to see to it that no new cases of infectious disease arise, by direct or indirect contagion, from any patient under his care. In enteric fever we have to do with a disease in which this is wholly practicable. Not only may the spread of the contagium be prevented, but the infecting principle can be wholly and absolutely destroyed. It is not too much to say that this disease, the great fever of the present historical epoch, is among the scourges of mankind which can, by organized effort, be stamped out; not in the wide sense that in the history of the past two centuries the plague was driven from Western Europe, that typhus disappeared from ships, jails, and armies, and that leprosy died out in Great Britain, but in a much more narrow and literal sense. There is abundant evidence in medical literature to show that organized prophylaxis, dealing with the water-supply, the milk, the drainage, and the excreta of individual cases, is capable of eradicating enteric fever from restricted localities.

In the second place, enteric fever is a curable disease. I use the word curable in an equally literal and narrow sense. It is my purpose here, having some slight personal knowledge of the matter, to endeavor to demonstrate that this proposition is true. I am not sure that I shall succeed. It is no easy thing to unsettle established convictions and to gainsay the conclusions of experience which seems to be based upon the daily observation of facts. Nor, indeed, have I the warrant of a sufficiently extended personal observation to do so.

Certain recent experiences in this disease have, however, greatly modified my views as to the part played by treatment, and it is because the treatment of which I am about to speak is, as a plan, so different from that generally employed, and because the results, as shown both by the course of the disease in individual cases and by the diminution of the death-rate, are so striking, that I feel impelled to urge this plan upon the attention of my professional associates who have not yet had an opportunity to try it. I know that enteric fever destroys, in the aggregate, more lives that could be saved than does any other acute infectious disease. I believe that, in the words of Baruch,[1] "We are standing to-day on the threshold of a great epoch in the treatment of this disease."

What has been the treatment up to the present time? Among innumerable plans, a host of drugs, and countless modifications of the methods of administering them, we may distinguish four general methods of treatment.

[1] Read before the Lycoming County Medical Society, at Williamsport, Pennsylvania, November 4, 1890.

[1] Reprint from the Transactions of the New York State Medical Society, February, 1889.

First, *the expectant plan*. Under this head must be included pure expectancy and those methods in which measures or medicaments are employed which are incapable, either by reason of want of force or by minimum dosage, of producing any physiological or therapeutic effect whatever. The disease is practically left to run its course, the duty of the physician being confined chiefly to regulating the hygiene and the diet.

Second, *the expectant-symptomatic*, or so-called *rational plan*, which is an extension of the expectant plan in that symptoms, as they arise, are treated by measures of more or less energy especially directed against them. Under this plan the physician's duties are manifold and perplexing, and the therapeutic measures, instituted in response to various indications, are complex, difficult, and often at variance among themselves.

Third, *the antiseptic plan*. This method has its origin in the fact that the evolution of the disease is due to the development within the organism of pathogenic germs, a process which continues until the soil is practically exhausted and the germs cease to grow. It recognizes the splitting up of complex chemical compounds entering into the formation of the fluids of the body, with the result of the production, on the one hand, of the pabulum necessary to germ-growth, and, on the other hand, of toxic substances foreign to the organism, to which the fever and the other symptoms are chiefly due. This plan of treatment claims to do all that the expectant and the expectant-symptomatic plans do, and undertakes to anticipate the development of unfavorable symptoms, by at least holding in check the cause of those symptoms. It embraces, first, intestinal antisepsis, and second, in theory, at least, constitutional antisepsis, and under certain forms has appeared to exercise a favorable influence upon the course and mortality of the disease.

Fourth, *the antipyretic plan*. This plan is based upon the theory, long since formulated by Griesinger, that the fever in great part controls the situation. It demands as an essential of treatment the restriction of the temperature-rise within limits, and insists upon the use of therapeutic measures to reduce the temperature whenever it attains a certain degree of elevation varying according to the views of different practitioners. These measures are, first, antipyretic drugs, and second, the external application of cold water. Under this plan the attention of the physician is directed to high temperature as at once the most serious symptom and the chief indication for treatment.

While these plans are in the main essentially different, it cannot be said that the boundary-line between them is absolutely fixed. Thus as intestinal antisepsis unquestionably exerts a favorable influence upon the intestinal symptoms, it constitutes to a certain extent a symptomatic treatment. And in the same way the symptomatic and antipyretic methods overlap.

Under one or the other of these four plans, or under some combination of them, enteric-fever cases are treated.

There are two tests of the efficiency of treatment in serious acute diseases; first, the effect upon individual symptoms and upon the clinical course of cases taken together in series; and second, the influence upon the death-rate. Submitted to these tests, none of the four general plans can be said to yield satisfactory results. Making due allowance for the fact that the enteric fever of childhood, from the second until the twelfth year, is a mild disease, with an extremely low mortality, and making further allowance for the large number of mild cases among adults which tend to recover without treatment, we all regard the disease under consideration as a serious one, often protracted, grave in itself, liable to dangerous complications, frequently followed by serious sequelæ, and terminating in a protracted convalescence. Many practitioners, having decided upon some one of the above plans of routine treatment, of which the details are modified to suit individual cases, come to regard it as the proper plan and to consider the results as on the whole satisfactory. Such confidence is occasionally seriously shaken. But the force of habit, the lack of a better method, and of the criteria by which to judge any plan, forces a return to the old method. Indeed, in testing the influences of therapeutics in the acute infectious diseases a wide experience and a critical scientific spirit are essential. If here and there a practitioner of large experience is satisfied with his results in the management of this disease, the same cannot be said of the profession as a whole. The very multitude of plans and remedies which overcrowd the journals shows a continued unrest and dissatisfaction with existing methods of treatment.

When we come to apply the second test, namely, the influence upon the death-rate, dissatisfaction with existing methods finds ample warrant. The rate of mortality in private practice is unquestionably lower than that among persons treated in hospitals. This is chiefly due to the previously better condition of private patients, and to the fact that they come earlier under treatment than do hospital patients, it being a matter of common observation that the mortality of cases neglected in the beginning of the disease is very much higher than that of those who early come under treatment. The statistics of private practice, however, are limited and difficult of access and are commonly based upon an insufficient collection of facts. Hospital statistics are more trust-

worthy; they are derived from facts observed by many different physicians, and in sufficiently large collections. They are, however, open to the objection that they probably indicate a death-rate somewhat too high.

The following reliable statistics collected from the great mass which is available indicate the hospital death-rate:

	Cases.	Deaths.	Mortality.
London Fever Hospital (21 years) .	8000	1519	18.9
" " " (9 years) .	500	80	15.9
Pauper Hospital at Homerton . .	1509	255	16 8
Stockwell Pauper Hospital . .	1223	301	22.6
St. George's " . .	387	76	19.6
Guy's " . .	295	57	19.3
University College " . .	163	29	17.7
St. Bartholomew " . .	635	104	16.3
St. Thomas " . .	445	70	15.7
Middlesex " . .	461	72	15.6
King's College " . .	318	39	12.2
Total number of cases in the London Hospitals . .	13 936	2602	17.8

Dr. Murchison found that of 27,051 cases collected from various sources, many of which have been included in the foregoing list, 4723 proved fatal, a death-rate of 17.45. Jaccoud, with a collection of 80,140 cases treated in Europe on the expectant plan, observed a mortality of 19.23 per cent. The General Hospital of Vienna, with 17,000 cases, has a mortality of 22.5; the hospital at Basle, with 1718 cases, a mortality of 27.3; and the principal Continental hospitals have, according to Dr. Cayley, a mortality varying between 16 and 25 per cent.

The English army statistics for six years, ending in 1877, are as follows:

	Cases.	Deaths.	Mortality.
On home service	545	131	24
On foreign service	1383	564	40.7
The Royal Navy for a period of six years, ending 1878 . . .	1414	110	26.5
Massachusetts General Hospital .	303	42	13.5

The statistics of the *Medical and Surgical History of the War of the Rebellion*, from 1862 to 1866, inclusive, show:

	Cases.	Deaths.	Mortality.
Among white troops . . .	75,368	27,056	35.9
Colored troops, 1864–1866 inclusive .	4094	2280	55.6

In the New York hospitals,[1] between January, 1877, and October, 1883, there were 1305 cases, with a percentage of mortality estimated by years, varying between a minimum of 20.1 per cent. in 1879 and a maximum of 30 per cent. in 1880.

The foregoing figures, covering a period terminating in 1884, show in general the results of the expectant and symptomatic treatment of enteric fever, although they probably include a small proportion of cases treated upon special antiseptic or antipyretic plans.

A second series of statistics, overlapping to some extent the foregoing in time and reaching down to the present, gives better results. They show the influence of the external application of cold as a therapeutic measure. Thus, Brand collected from various reliable sources 19,017 cases, treated by all kinds of cold baths, with a mortality of 7.8 per cent; Bouveret and Teissier, with a mixed expectant-symptomatic and antipyretic treatment (1873 to 1881), 629 cases, mortality 16.5 per cent.; and 1882 to 1887 inclusive, cold baths in severe cases, 376 cases, mortality 6.9 per cent.

Vogl's statistics, from the Military Hospital in Munich, are as follows: Expectant treatment from 1841 to 1868, 5484 cases, and a mortality of 20.7 per cent.; intermediate, with water, 1868 to 1881, 2841 cases, mortality 12.2 per cent.; and baths and internal antipyretics, 1875 to 1881, 702 cases, with a mortality of 7.6 per cent.

Ziemssen's statistics from 1877 to 1887 (graduated cold bath and antipyretics), show 2000 cases, with a mortality of 9.6 per cent.

In startling contrast to the above is a third series of statistics, dating back more than a quarter of a century, and including, first, the cases of Brand, and later of those who, under the force of incontrovertible facts, have gradually fallen into the line of treatment devised and so long advocated by him. Thus:

Teissier, 1887, strict cold bathing, 139 cases, mortality 5 per cent.

Vogl, in 1880, strict cold baths, 428 cases, mortality 2.7 per cent.; 1882 to 1887, strict cold baths, 141 cases, mortality 3.5 per cent.; 1882 to 1887 (a second series), increasing baths and the abolition of internal antipyretics, 144 cases, mortality 4.1 per cent.; Naunyn, strict cold baths, 145 cases, mortality 6.9 per cent.; Brand, cases collected from various sources, with strict cold baths, 2198 cases, mortality 1.7 per cent.

The last-named observer shows from an analysis of the same cases, omitting those not treated before the fifth day, 2150 cases, without a death.

The general statistics of the strict cold-water treatment show a reduction of the mortality to 3.9 per cent. These figures are obtained by Brand from twenty-three German and French designated sources with 5573 cases, this number undoubtedly containing many imperfectly-managed cases. (Baruch.)

The number treated strictly according to the method of Brand by himself, Jurgensen, Vogl, and others up to January, 1887, amounted to 1223 cases, of which 12 died, a mortality of 1 per cent., not one of the fatal cases having come under treatment before the fifth day.

That the modifications of the expectant-symptomatic method brought about by the use of antiseptics and antipyretics have not greatly reduced the death-rate is shown by the fact that in Philadelphia during

[1] Delafield: Medical Record, November 17, 1883.

the year 1889 there were reported to the registry office of the board of health 4631 cases, with 736 deaths, a mortality of 15.9 per cent.

The mortality statistics of enteric fever studied in connection with the prevalent methods of treatment justify the conclusions that under pure expectancy recovery will take place in about seventy per cent. of the cases: that about fifteen per cent. will die despite the treatment; and that the result in the remaining fifteen per cent. will depend to some extent upon the management of individual cases.

It is impossible to foresee at the onset of any particular case what its course is going to be, either as regards intensity or complications. The real objection to the expectant-symptomatic treatment is that it is not directed against the cause of the morbid manifestations. Too often the appearance of grave symptoms indicates mischief that is already past remedy. The aim of treatment should be not to control serious symptoms as they arise, but by acting upon the cause of the disease from the beginning to anticipate their development. This I have for some years insisted upon in speaking of the treatment by carbolic acid and iodine, originally suggested by Bartholow. If the claims made by Brand and his followers, that under the strict cold-bath treatment the course of the disease is essentially modified, that the symptoms are milder, that complications and sequelæ do not arise, and that the death-rate, as shown by large series of cases reported by a number of competent observers, undergoes the startling reduction indicated by the figures I have cited—if these claims can be substantiated, there can be no question as to the duty of the profession toward the sufferers from this disease.

We cannot disregard the array of facts marshalled in the literature of the past five years. That a routine treatment so novel should be officially recognized by the Prussian War Department is important testimony to its value. Still more important is the fact that French military surgeons who, as prisoners at the close of the Franco-Prussian war, had the opportunity to observe Brand's treatment at Stettin, adopted, and have since practised, this treatment in the military hospitals of their own country.

What, then, is the method of Brand? It consists in the following systematic procedure[1]:

Whenever the temperature taken in the rectum reaches 102.2° F. (39° C.) the patient is placed in a bath of 65° F. A compress, wet with water about five degrees lower, is placed upon the head, or water at a lower temperature is poured upon the head and shoulders. The patient remains in the bath fifteen minutes, during which time he is systematically rubbed by the attendants and encouraged to rub himself. At the expiration of that time, he is removed from the bath, and wrapped in a coarse linen sheet over which a blanket is folded, the extremities being thoroughly dried and rubbed. A little wine or spirits is then given. This is repeated every three hours, unless the temperature remains below 102.2° F. The alimentation is liquid, nutritious, and carefully regulated. No drugs are administered.

Glenard[1] gives the following outline of the technique of the treatment by cold baths:

"If the diagnosis of typhoid fever is probable, recourse should be had to the baths, whatever may be the symptoms. The full tub should be placed in the ward or chamber, parallel to the bed at a distance of one or two metres, the floors properly protected by oilcloth, and a screen placed between the bed and the bath-tub. A sufficient quantity of water should be used to cover the patient's body to the neck. It should be of a temperature of from 64.4° to 68° F. (18° to 20° C.). The baths should be prepared without disturbance or noise. There should be placed on the floor near the head of the tub two pitchers of cold water of a temperature of from 46.4° to 50° F. (8° to 10° C.), each containing four or five quarts (litres). A glass of water should be at hand. The first bath should be given preferably about four o'clock in the afternoon, unless there is some urgent reason for selecting a different hour, and the physician should be present. The rectal temperature is taken, the urine is voided, and the patient is assisted into the full tub, the screen having been removed. If there is perspiration the patient is dried before entering the bath. Cold water from the pitchers is poured upon the head and the back of the neck, for one or two minutes, the amount being from two to three quarts (litres). Then a swallow of cold water or red wine is given. This being done, the whole surface of the body is briskly rubbed with a sponge or brush and the patient is made to rub his abdomen and chest. These frictions stimulate the peripheral circulation, prevent the accumulation of heat at any one point, moderate the sensation of cold, and help to pass the time; they are not indispensable. Shivering appears, as a general rule, in between eight and twelve minutes; this is a necessary evil to which too much attention is not to be paid. Toward the middle of the bath, or at its termination, cold water is again poured over the head and neck. The time occupied ought to be at least fifteen minutes, longer if the head is still warm and the cheeks red, or if the temperature of the patient was very high before the bath.

"The patient should leave the bath without precipitation. He cannot take cold, thoracic complications are caused by typhoid fever and not by

[1] Le Bulletin Médicale, February 26, 1888.

chilling. The air of the apartment should be pure and not too warm; the window should be opened in the intervals between the baths, during the bath it ought to be closed. On leaving the bath, the patient should be gently dried with a towel. The bed should be carefully made during each bath. If on returning to the bed shivering takes place, the limbs should be rubbed and a hot bottle placed at the patient's feet. A cold compress, covered with oil-silk or flannel, should be placed over the abdomen, and a little warm nourishment administered.

"Three-quarters of an hour after the bath the rectal temperature should again be taken. If, however, it is found to be below 101° F. (38.5° C.), it is not necessary to take it again for three hours.

"Alimentation should consist of the following articles: Milk diluted with coffee or tea or cocoa (a quarter of a litre at each administration); thoroughly cooked gruel, oatmeal, tapioca, or vermicelli; veal, mutton, or chicken broth, freed from fat when cold and reheated at the moment of administration. As a drink, pure cold water should be given; the indication for wine or spirits is urgent only in cases that are subjected to this treatment late in their course. If the patient does not sleep, or sleeps badly, he is to have a draught of iced water, and the abdominal compress is to be changed every quarter of an hour. The discharges from the bowels are to be preserved for inspection, and the total quantity of urine may be collected in the same vessel. Neither age, sex, menstruation, pregnancy, nor sweating (except that which occurs at the end of defervescence) in any way modifies the treatment. In women who are weaning their children, cold compresses should be applied to the breasts and frequently renewed. If diarrhœa persists, it is to be combated by cold compresses, which may be kept cold by the aid of a bladder of ice. If there is constipation, it is to be treated by cold enemata, and, if these fail, by enemata consisting of one part of cold water and one part of fresh ox-gall.

"When the temperature before the bath is very high, or if the fall forty-five minutes after the bath is less than 1.8° F. (1° C.), the bath must be prolonged to eighteen or twenty minutes. It is very rarely necessary to modify the general formula. After the temperature does not exceed 102.2° F. (39° C.), but yet reaches 101° F. (38.5° C.), it is necessary to treat these slight exacerbations by baths of 68° F. (20° C.), and of five minutes' duration in order to prevent the prolongation of the fever or the occurrence of relapse, and to shorten convalescence. If relapse occurs, it must be treated according to the general formula. When the temperature no longer exceeds 101° F. (38.5° C.), defervescence being established, the baths are discontinued, and the patient should be treated as convalescent, but is to be kept in bed until the temperature has not exceeded 100.4° F. (38° C.) for four days. He may then rise and in a short time walk in the open air; he may prolong his promenades according to his strength, and one will be struck by the rapidity with which his strength increases after every outing. Proper precautions are to be taken against cold. As to alimentation, already during defervescence there may be added to his soup, milk, or bouillon, either one or two raw eggs daily, or, a little later, one or two teaspoonfuls of scraped raw meat or a little toasted bread or biscuit; but the aliment must always be given in liquid form.

"The *régime* of the convalescence should be gradually established, and may consist of solid food after the temperature has not risen above 100.4° F. (38° C.) for four days. At this period the intervals between the feedings should be at first three hours during the day; afterward one regular meal daily may be given; and a little later the patient may have roast beef and fish, morning and evening, and bread in small quantities. The appetite is excellent, and it is necessary to control it. For the first two days of the convalescence the temperature is to be taken as before, after that, for a week, morning and evening. At the end of that time temperature observations may be discontinued.

"During the treatment by baths, one attendant is required for the day and one for the night; these duties may be fulfilled by members of the family. In a hospital one bath-tub may be made be used for a dozen patients, but it is better to use one for six patients. Two attendants are sufficient for twelve patients. It is not necessary to renew the water of the bath every three hours; once in twenty-four hours is sufficient. The patient treated from the beginning in this manner, never suffers from fæcal incontinence. As a rule, the patient should pass his water before entering the bath. During epidemics, the water of the bath, if it is not soiled, should serve for several patients, and should only be renewed two or three times a day."

This is the line of treatment to which, rigorously carried out, the extraordinary results which I have indicated are ascribed. That it seems heroic, thus briefly stated, cannot be denied. That it is heroic to those who see it practised for the first time, is more than true. Preconceived notions in regard to the management of typhoid cases are violated. The frequent disturbance for the purpose of taking temperatures and bathing, the fact that the patients are compelled to rise from their bed and with the aid of the attendants to step into the bath, the pallor, shivering, and the blueness of the extremities which shows itself during the course of the bath and continues for a varying time after the patient is put to

bed, demand conviction on the part of the physician, and the courage of conviction to continue.

It is only when the favorable effect upon the condition of the patient is seen, and when we reflect that in every hundred cases at least ten lives which would be lost under the expectant-symptomatic treatment are saved by strict cold bathing, that we dare to proceed.

What is the effect upon the course of the disease in cases treated from the beginning, that is, before the fifth day? Brand declares that the classical picture of typhoid fever is no longer seen. It may be objected to this that we do not get our cases before the fifth day; and even if they come under observation so early a positive diagnosis cannot always be made at that time. Only in garrison life and in epidemics will a treatment so radical be justifiable at the onset of a vague febrile disease. But Brand's statement is true of cases in which treatment is instituted at a later period, even so late as the middle of the second week. After six or eight baths the familiar picture is no longer seen. Delirium ceases, stupor gives way to light somnolence from which the patient is easily aroused with a bright expression and a clear mind. The tongue becomes moist and clean and remains so. There is desire for food, and very commonly a complaint of hunger. The abdomen is not tympanitic. Diarrhœa is rarely excessive or troublesome. In short, there remains, in the words of Brand, of the ordinary picture of typhoid nothing more than (*a*) a moderate fever, (*b*) an unimportant bronchial catarrh, (*c*) enlargement of the spleen, (*d*) the rose rash, and (*e*) infiltration of the intestinal glands. Everything else is prevented, and what might have been a severe case runs its course as a mild one if the patients are brought under treatment sufficiently early. Exceptions to this statement occur only when complications develop at the onset. There are rapid wasting and progressive anæmia, as in all prolonged febrile diseases, but severe enteric fever is changed to mild, the mild to a still milder form. This is brought about through the control of the temperature and by preventing disturbances of normal functions. The treatment is directed against the typhoid process as an entirety.

It does, it is true, not only reduce the temperature; the repetition of the bath also *controls* the temperature and keeps it down. But the bath does much more than this. It acts upon the nervous system in such a manner as to enable it to withstand the toxic influences of the infecting principle and the products of its evolution. This it doubtless does by the action of cold water upon the peripheral nerve-endings, a reflex stimulus being transmitted to the nerve-centres presiding over the circulation, respiration, digestion, excretion, and nutrition. This general reinforcement of function is shown by improved action of the heart, the first sound continuing distinct, the pulse being slower and more regular, and the improvement in the arterial tension showing itself by an absence of dicrotism; by persistence of appetite and digestive power, permitting freer alimentation without gastric disturbances; by deepening and slowing of the respiration; and by the absence of nervous symptoms, the increased excretion, the prevention of complications, and the rapid convalescence.

As was pointed out by Jürgensen, every attempt to deviate from the routine treatment as above laid down is followed by less satisfactory results. The treatment thus stands by itself as a definite procedure, to be distinguished from treatment by graduated baths, the cold pack, cold affusions, spraying, and other hydro-therapeutic measures. It is especially to be looked upon as something distinct and different from the antipyretic treatment. Upon this Brand and his followers insist.

In a service at the German Hospital of Philadelphia, extending from February 1st to July 15th of the current year, I had the opportunity to treat fifty cases of enteric fever. Of these, ten, for reasons chiefly connected with my want of experience in cold bathing, were treated either upon the expectant method or by means of carbolized iodine. The remaining forty were treated in accordance with the method of Brand, with two modifications: First, each case admitted prior to the tenth day of the attack received one or two laxative doses of calomel; second, the temperatures being taken in the axilla or mouth instead of in the rectum, the bath was regularly administered every three hours so long as the temperature reached 101.5° F. Otherwise the routine method above described was carried out in every particular.

Of the ten cases treated according to the old methods, one died, the patient being a man aged thirty-three years, admitted at the end of the second week of the attack, and already suffering from an intestinal hæmorrhage. Death occurred on the third day after his entrance to the ward.

Of the forty cases treated by bathing, all recovered. One case suffered two relapses and was much protracted. A second case suffered a single relapse. Intestinal hæmorrhage occurred in two cases. Upon the supervention of hæmorrhage bathing was discontinued. The average number of baths in each case was forty-two, the smallest number, ten, the largest number, one hundred and thirty-eight. These cases showed the favorable effects of bathing in every instance. As a rule, the patients did not object to the baths. When they did so, the objections ceased after a few baths had been administered. Complications were trifling, there were no sequelæ,

and in every case the convalescence was rapid and satisfactory.

As I have already taken up much time, I reserve an analysis of the details of these cases for future publication. Suffice it to say that the statements made by European observers were fully realized in this series of cases. Severe symptoms were mitigated, and mild cases ran a most favorable course.

For the sake of comparison I submit the statistics of some of the hospitals in Philadelphia for the same period of time and for a corresponding period of last year.

Hospital.	Year.	Number of cases.	Average number of days in hospital.	Number of deaths	Percentage of mortality.	Treatment.
The Pennsylvania Hospital,[1]	1889	31	38	5	16.1	Expectant-symptomatic.
Do.	1890	46	37	6	13.04	
The Episcopal Hospital,	1889	69	44	9	13.04	Mixed, intestinal antiseptic. Internal and external antipyretic; no baths.
Do.	1890	40	50	5	12.5	
St. Agnes Hospital,	1889	19	36	2	10.5	Expectant-symptomatic.
Do.	1890	15	34	4	26 6	
The German Hospital,	1889	41	36.5	4	9.75	Expectant-symptomatic.
Do.	1890	50	36.9	1	2	10 cases carbolized iodine; 40 strict cold baths.

Two hundred and seventy-one cases on expectant-symptomatic treatment with some antiseptics and applications of cold water, and with 36 deaths, a mortality of 13.29 per cent.; 40 cases with strict cold bathing; no deaths.

Since the 15th of July the strict cold-bath treatment has been uniformly followed in the German Hospital by my colleagues, Dr. Trau and Dr. Wolff, twenty-four cases having been treated without a death. The statistics of the German Hospital then as regards enteric fever are, from February 1, 1890, to this date, sixty-four cases treated by the cold baths without a death.

In conclusion, the objections which have been urged against this method of treatment are of the general nature of those usually brought forward against radical departures from established therapeutic customs.

First, the statistics are questioned. This objection can no longer be sustained. A large number of independent observers have fully confirmed the general results obtained by Brand.

Second, it is asserted, *a priori*, that the typhoid of this country is not sufficiently severe to demand so radical a treatment. The statistics which I have presented sufficiently disprove this statement. Furthermore, it must be insisted upon that it is impossible to foresee the severity of any particular case at the outset of its course. The treatment by the method of Brand tends to make every case a curable one.

Third, another *a priori* objection is that patients in this country do not bear cold bathing as well as the French and Germans. It is a matter of surprise that this can be seriously urged as an objection to a treatment incontrovertibly shown to be as efficient as the one under discussion. Furthermore, our experience in the German Hospital of Philadelphia does not bear this objection out. It is true that certain cases do not react promptly, and that women react less promptly and less satisfactorily than men. In no case in my series, however, did the delay in reaction after the patient was put to bed cause the slightest apprehension on the part of the attendants.

Fourth, it is inconvenient, and demands an amount of experience and labor on the part of the attendants not easily to be had in private practice and in some public institutions. Objections of this nature cannot stand against the lowered rate of mortality.

Finally, the opposition of the patients themselves and of their friends may be urged as an obstacle to any attempt on the part of medical men to introduce the treatment into private practice. This is no real objection; it is a mere difficulty that will vanish so soon as the profession generally recognizes in the method an efficient means of saving many lives, and lends its weight to the advocacy of the plan among the people. These remarks are intended to contribute to that desirable end.

[1] For these statistics I beg to express my thanks to Dr. Meigs, attending physician, and Dr. Scott, resident physicians of the Pennsylvania Hospital; to Dr. Knight and Dr. L. H. Adler, of the Episcopal Hospital; Dr. Grove, of St. Agnes; and Dr. Frese, chief resident physician at the German Hospital.

TREATMENT OF GENERAL SEPTIC PERITONITIS.[1]

By W. L. ROBINSON, M.D.,
of Danville, Va.

The subject of the treatment of general septic peritonitis is full of interest to every surgeon, for prompt decision and action determine the fate of the patient. No wonder, then, that the alarm is repeatedly sounded to warn the general practitioner. It is not alone the cases that are lulled to rest and deceptive security by opiates which confront us, but often the most dangerous condition is that in which the patient is, without opiates, quiet, non-febrile and contented, expressing himself as much better, sub-

[1] Read before the Southern Surgical and Gynecological Association, November 12, 1890.

sequent to a chill and fever. In such conditions either suppurative peritonitis or a secondary abscess has probably commenced to form.

I recall two cases of appendicitis, abscess, and suppurative peritonitis which I was called to see during the last few months. One had used salines and opium alternately for a week, and had had fever and a chill on the day that I saw him. On the next day he was perfectly comfortable, he had no fever, the pulse was quiet, the tenderness had diminished, and there seemed to be improvement. An operation was performed, followed by irrigation and drainage, but the patient died two days later from septic peritonitis and secondary abscess.

The other case on the second day of the attack had a chill, which recurred in six hours, and was followed by collapse and delirium. After restoration by the use of hot bottles, hypodermic injections of whiskey and strychnine, I urged an operation, but freedom from pain, diminished tenderness, absence of fever, a fairly good pulse, some appetite, and no nausea, prevented the attending physician from consenting to an operation until the third day, when, although there was no change save an increase in the size of the tumor, he yielded. There was a considerable amount of pus in a sac, which was as thin as paper and formed by adhesions. The cavity was irrigated and drained, but the patient died in two days. At the autopsy a gangrenous condition of the intestines and suppurative peritonitis were found. Why this sudden cessation of pain and fever and the comfortable condition of the patient?

We all have noticed in puerperal peritonitis the absence of pain and the disproportion between the pathological condition and the slight amount of tenderness on pressure. Septic conditions may cause fever, restlessness, prostration, etc., but seldom pain; and when pain is present in puerperal peritonitis, it is only from pressure in a distended sac. Indeed, in this disease pain is so uncertain a symptom that he who relies upon it in diagnosis will, I fear, often be misled.

I believe that in the adult the three principal causes of general septic peritonitis are gunshot wounds, appendicitis, and pelvic inflammations. Of course, many other causes indirectly produce it, such as a blow resulting in abscess, tubercular inflammations, etc.; indeed, any internal or external influence producing an abscess, which ruptures, may cause it.

I fully concur with the views that Dr. Lydston has expressed in a recent article, in which he denies the existence of idiopathic peritonitis in children, and regards blows, falls, etc., as causes of suppurative peritonitis and appendicitis. I believe, as he does, that suppurative peritonitis is more frequent than we imagine, and that we often recognize it too late.

I will refer to gonorrhœa as a cause of septic peritonitis in women, and state that I have had case after case in which I could trace the peritonitis to nothing else. Now, it may be asked, Why does not gonorrhœa always produce septic peritonitis? One reason is, I think, that adhesions form between the ovaries and the tubes, and that these adhesions confine the gonorrhœa to the tubes. Gonorrhœa in the female does not always invade the uterus any more than in the male it invariably attacks the bladder.

Now, as to the treatment. I would first say that preventive operations should not be neglected. If either appendicitis, hepatic abscess, or pus-tubes is diagnosed, or if pus in the abdominal cavity is suspected, operate. Exploratory incisions may be dangerous, but far less so than inattention to either of the above conditions. If there is one fact established in surgery, it is the importance of evacuating pus, no matter in what part of the body it is found. Abdominal section, irrigation, and drainage is the accepted treatment.

You will often find not only extensive adhesions, but pus-sacs. Insert your fingers as gently as possible, separate the intestines carefully, yet effectually, irrigate thoroughly, and if bleeding is excessive pack the cavity with iodoform-gauze; if bleeding is not excessive, use drainage-tubes. The gauze can be removed in small amounts every day. The drainage-tube should be cleaned antiseptically every six or eight hours, and gently rotated. The time to remove it will be indicated in each case. Pus-sacs should be aspirated or, if possible, brought to the surface and emptied. Always be prepared, in case of injury to the bowel, to resect, anastomose, or treat as may be indicated. After operations I usually give a saline daily to prevent adhesions from re-forming.

In some cases you can do only a partial operation. In such tear as many adhesions as is prudent, irrigate, and after improvement in the general condition of the patient you will be able to complete the operation.

Again, in those cases in which there is extensive and distressing tympanites, there is a most troublesome condition to deal with. The muscular coat of the bowel is paralyzed by overdistention, and purgatives have little effect. In such cases I would be disposed to adopt the suggestion of Dr. Davis, namely, open the bowel and flush out with hot water.

Illustrative of the good that can be accomplished by the partial separation of adhesions, I will report a case which I was called to see in consultation three or four weeks ago:

The patient was a young married woman, and had never been pregnant. She had been treated for two weeks for fever, and was seemingly better, but later developed peritonitis, which spread rapidly, and was accompanied with constant pain, much aggravated by defæcation and urination. At the expiration of the fourth week I saw her. The doctor said she was better, yet 150 drops of laudanum had failed to give relief the previous night. Her stomach would retain nothing. Her abdomen was swollen, tympanitic, and fluctuating. I elicited from her husband that he was convalescing from an attack of gonorrhœa. I obtained consent to operate on the next day, and gave a saline, which caused two movements. I should have stated that the temperature was 102°; pulse 130. On the following day the temperature was still high, the pulse more frequent and feeble. The physicians present did not think she would live through the operation. However, I operated. The tissues bled at every cut. The peritoneum was firmly adherent to the abdominal walls; the bowels were generally adherent, and it was with great difficulty that I was able to introduce my finger. I broke up the adhesions as gently as possible, partially irrigated, and put in a drainage-tube. The breaking up of the adhesions caused considerable bleeding, the blood being mixed with pus. She reacted slowly, but on the following morning her pulse was less than 100 and temperature 99°. She continued to improve, a saline being given daily to prevent the adhesions from re-forming. On the seventh day I was confined to my bed and remained there a week. The patient, on my return, was suffering from pain, especially during defæcation and urination, but said that she had had no movement of the bowels, except a small one that morning, for five or six days. I gave her a full dose of sulphate of magnesium, and after six stools all her symptoms disappeared, and she was sitting up when I left her. I know I did an incomplete operation, but to have done more would have killed my patient. Should it become necessary, I can complete it now that she is more able to stand it.

Regarding gunshot wounds of the abdomen, I will only say that he who has once opened an abdomen for such an injury will not hesitate to operate when his second case is presented.

OPERATION FOR ANKYLOSIS OF THE TEMPORO-MAXILLARY ARTICULATION.

By CHARLES B. PENROSE, M.D., Ph.D.,

SURGEON TO THE GERMAN AND GYNECEAN HOSPITALS, AND TO THE OUT-PATIENT DEPARTMENT OF THE PENNSYLVANIA HOSPITAL, PHILADELPHIA.

Ankylosis of the temporo-maxillary articulation may be the result of an injury, such as a severe sprain or concussion; or it may be due to arthritic inflammation, followed by plastic adhesions, which become converted into fibrous, cartilaginous, or osseous tissue.

If the ankylosis is caused by fibrous bands, these can be divided subcutaneously with a tenotome passed into the articulation, as has been done by Spariton.[1] The condyle has also often been excised, and with favorable results in most cases.

Mears[2] has proposed the operation of dividing the ramus of the jaw by an Adams's saw introduced through the mouth, and excising, in this way, the condyle with the coronoid process and sigmoid notch.

The operation, first proposed by Esmarch, of making an artificial joint in the lower jaw by the removal of a wedge-shaped piece of bone, has been successfully done a number of times. Indeed, most of the operations which have been performed for the relief of ankylosis of the temporo-maxillary articulation have had a fair percentage of successful results, though the methods varied. Even the plan of Rizzoli, of merely cutting through the jaw with powerful forceps introduced in the mouth, without removing any portion of bone, has been attended with success. The operations, however, in which a portion of bone is removed, and thus the formation of a false joint is facilitated, are preferable.

When there is complete ankylosis with entire loss of motion of the jaw, it is often difficult to determine on which side the lesion exists. And though the stiffness may have been primarily confined to one temporo-maxillary articulation, yet the other joint may become secondarily ankylosed from the changes following long-standing disease. It is probable that this occurred in the case which I am about to report, for the ankylosis must at first have been confined to the right side, since the first operation, performed on this side alone, was followed, for a short time, by good motion of the joint.

A man twenty-eight years old was admitted to the Pennsylvania Hospital, April, 1890, with complete ankylosis of the temporo-maxillary articulations. The upper teeth were firmly set upon the lower teeth, and he was unable to pass the blade of a penknife between them. He could take only liquid food. He suffered constantly from dyspepsia and from sore-throat, which could not be relieved by local treatment. His family history and his general personal history were good. Four years previously he had had an attack of acute articular rheumatism of several months' duration. Most of the joints of the body were affected, those of the jaw being the last attacked. The movements of the jaw rapidly became stiff, and by the time convalescence was complete he was unable to open his mouth at all. Four months after the appearance of complete ankylosis he was operated upon in New York, and, as he states, the condyle of the lower jaw on the right side was removed. After this he had fair motion of the jaw, but the stiffness gradually returned, and in two months was as complete as before operation.

The scar of this operation was barely perceptible

[1] Lancet, April 16, 1881.

[2] American Journal of the Medical Sciences, October, 1883.

upon the right cheek. The incisions were evidently similar to those which I subsequently made. There was no pain and no swelling of either temporo-maxillary articulation, and it was impossible to determine whether the ankylosis existed on only one or on both sides. He said that he thought the left joint was normal and that his disability was caused by ankylosis of the right side, as at the time of the first operation. There was no perceptible muscular rigidity or stiffness.

Operation.—A vertical incision was made in front of the right ear, and a horizontal one meeting the upper end of the first incision was carried along the lower border of the zygoma. The flap thus formed, with the parotid gland, was drawn down, and the posterior fibres of the masseter muscle were cleared away with a periosteal elevator. The position of the temporo-maxillary articulation was thus exposed. There was complete bony union between the neck of the lower jaw and the temporal bone, and no condyle was discovered. A small trephine was applied to the centre of the ramus immediately below the sigmoid notch, and a button of bone was removed. The bridges of bone on each side of this opening were then divided by a chisel.

As, notwithstanding this division of the right ramus, it was found impossible to open the mouth, and as the difficulty did not appear to be caused by any muscular contraction, a similar incision was made upon the left cheek. The upper part of the left ramus was exposed, and there was found to be firm bony union between the condyle and the temporal bone. A portion of the neck one-third of an inch in thickness was resected by means of a chain saw. As there then appeared to be some contraction of the temporal muscle which prevented free opening of the mouth, the attachment of this muscle to the coronoid process was divided. After this it was possible to separate easily the upper and lower incisor teeth a distance of more than one inch.

There was free, though easily controlled, bleeding during the operation. The wounds were drained with small rubber-tubes and closed with silkworm-gut sutures. Primary union took place. Seven days after the operation all dressings were removed, and the patient was able to eat the ordinary hospital diet, which included beefsteak of the average toughness.

As during sleep he was unable to keep the jaw in motion, and thus prevent union or adhesion and contraction, the jaws always became stiff during the night, and in the morning he found difficulty in opening the mouth to the same extent as on the previous evening. He was, therefore, given a wedge of rubber varying in thickness from one-half to one inch, to place between the teeth on retiring. Three weeks after the operation he was etherized and the mouth was forcibly opened to the fullest extent, in order to break thoroughly whatever adhesions might have formed. He continued to use the rubber wedge for four months, when the tendency to stiffness at night disappeared and he was able to do without it. When last seen, six months after the operation, he could eat any kind of food; he constantly chewed tobacco; and he had three-fourths of an inch space between the incisor teeth. He was perfectly comfortable, except that after much chewing he had slight pain in the region of the artificial joints. There seemed to be no tendency to any further closure of the mouth, and the scars upon the cheek caused no disfigurement.

A SUCCESSFUL CHOLECYSTECTOMY FOR IMPACTED GALL-STONES AND INTRA-MURAL ABSCESS OF GALL-BLADDER.

BY J. L. DAWSON, JR., M.D.,

PROFESSOR OF THE PRINCIPLES AND PRACTICE OF MEDICINE AND OF CLINICAL MEDICINE IN THE MEDICAL COLLEGE OF THE STATE OF SOUTH CAROLINA, CHARLESTON, S. C.

OPERATIVE procedures for the removal of the gall-bladder are sufficiently rare to render the following case of interest, and successful results are so seldom obtained that I desire to place this one on record:

History.—Mrs. L., white, aged thirty years. Always suffered from hysteria at her menstrual periods. She was under constant observation, needing medical aid at every menstrual flow. She was the mother of two healthy children. Vaginal examination disclosed a prolapsed left ovary, subacutely inflamed. At her menstrual periods she became very nervous, complaining of great pain in the left side of the pelvis, and having frequent convulsions, hysterical in their nature. Being susceptible to mental shock, the most trivial anxiety, such as the illness of her children, or any slight worry, would produce an hysterical attack. She was of costive habit, but to no great degree, and she had no disorder of the digestive tract. She went to the mountains during the summer of 1889, and gained several pounds in weight.

On June 2, 1890, I was summoned to see her and found that she had just returned from Savannah, Georgia, where three days previously she had been caught in a shower, during which her clothes became soaked. Her menstrual flow, which had just begun, was immediately checked. She had also received a severe mental shock by the sudden disclosure of some family secrets. I was not surprised to find her in an hysterical convulsion, and did not examine very carefully into the cause of the abdominal pain of which she complained. This pain was dull and aching in character, not acute or spasmodic. She was put upon the bromides, and things went well for seventy-four hours, when she had a severe rigor, followed by a rise of temperature to 104°, and profuse sweating. These symptoms presented themselves on the next day at about the same hour, and again on the third day, the temperature falling after the sweat.

Presumably a case of malarial quotidian fever, she was given quinine. This drug had no effect and the rigors became more frequent, the temperature remaining above 102°, and nearly stationary. A mercurial purgative was given, which emptied the bowels, and the temperature was controlled with phenacetin. On June 15th I discovered a tumor in

the right hypochondriac region extending obliquely to the middle line, and reaching an inch below the umbilicus. Its outlines were clearly definable, it being pear-shaped, with the base downward and forward. Her rigors and the elevation of temperature continuing, with the advice of Dr. Manning Simons, whose opinion as a consultant I sought, we passed a fine aspirating needle into the swelling and removed a few drops of sanious fluid. The abdomen was very tender, the slight manipulation necessary for this operation causing exquisite pain. The stools, which were frequent throughout the illness, were carefully examined. They were fluid, stained with bile, and threw no light on the diagnosis.

On the following morning the aspirating needle was again inserted, this time not in the base of the tumor, but in the side and from the median line. We now readily obtained a clear watery fluid of low specific gravity, and no color. This fluid was examined chemically and microscopically. It consisted of a strong solution of sodium chloride, and was devoid of albumin. The microscopical examination was negative, nothing being found save a few epithelial cells. Subsequently a large Dieulafoy's aspirator was used. The needle was entered at the point of the last puncture and two ounces of a thin muco-sanious fluid were obtained. This fluid contained a slight amount of pus and blood, otherwise the composition was the same as that previously obtained. For thirty-six hours the patient's condition improved. The temperature fell from 104° to 99°, and the rigors ceased. Locally the tenderness over the seat of the tumor increased, due probably to the punctures.

On the evening of June 22d the temperature again rose to 104° after a severe chill, and it was thought advisable to temporize no longer.

Operation, June 23, 1890.—The patient was anæsthetized with chloroform and placed upon the operating-table. An incision three and one-half inches in length was made over the tumor parallel to the median line, and corresponding to the centre of the right rectus muscle. It extended from the margin of the last true rib to one inch below the umbilicus. After the hæmorrhage was thoroughly controlled the peritoneum was divided on a director to the full length of the wound. The tumor lay just beneath the centre of the incision and extended upward along the under surface of the liver toward the posterior border. It was slightly adherent posteriorly, at its neck, and quite adherent superiorly to the under surface of the liver. After being carefully detached from these adhesions by passing the finger around it, the pedicle was transfixed and securely ligated with a stout silk ligature. The pedicle was then cut through and the tumor removed. The hæmorrhage, which was a slight general oozing, was readily controlled by the pressure of sponges soaked in hot bichloride solution. The peritoneum, which had become very much thickened by inflammation, was united with catgut and the edges of the abdominal wound were brought into perfect apposition with deep silver and superficial catgut sutures. The wound was dressed with iodoform-gauze and absorbent cotton supported with a flannel roller. The strictest antiseptic precautions were used throughout.

The tumor was the gall-bladder hypertrophied and thickened by inflammatory products. Its walls were from three-fourths to seven-eighths of an inch thick, and contained an abscess cavity posteriorly about the size of a large filbert. This abscess had opened into the cavity of the gall-bladder and had thinned its walls so that rupture into the general cavity of the peritoneum was imminent. The sac contained three large gall-stones, weighing respectively, seventy-nine, eighty, and eighty-one grains. These stones were polyhedral and showed well-marked facets. They completely filled the cavity and occluded the orifice of the duct. The cavity also contained two drachms of muco-pus unstained with bile, and no trace of biliary coloring matter was discernible. The hypertrophied cyst measured four and three-quarters inches in length by two and one-half inches in its greatest width.

Result.—The patient reacted well from the operation. On the third day a large evacuation of the bowels followed the administration of an enema. The fæces were well formed and of a bright yellow color. She retained nourishment well. On the morning of the fourth day she passed about four ounces of almost pure blood from the bowels. This hæmorrhage occurred again during the subsequent night. She then began to improve rapidly, her whole aspect becoming better. Her temperature, however, did not become normal, rising a degree to a degree and a half every evening.

At the end of a week the wound was dressed. It had healed superficially, but there was a suppurating tract extending upward through which flowed a considerable quantity of creamy pus. In a few days this pus became thin and mixed with bile, a temporary biliary fistula being established.

The flow of bile through the wound ceased in about ten days but the fistula remained patent. The temperature continued to rise in the evening and the case became complicated by a large bedsore which formed over the sacrum. On the forty-eighth day after the operation the silk ligature passed out through the fistulous tract. The temperature then returned to normal and the patient made a good recovery, being now, three and one-half months after the operation, quite well, and having gained twenty pounds in weight. Her bowels act well and the stools contain the usual amount of bile. She has had no return of hysterical symptoms.

REMARKS.—The diagnosis in this case was an extremely difficult one. We had a patient known to have a subacute ovaritis, presenting symptoms of sepsis and concealed abscess, with no sign of derangement of the liver or intestinal tract. The appearance of the tumor and the fluid aspirated therefrom suggested a hydatid growth which had broken down and suppurated. The gall-bladder had not performed its function for years and yet there had been no evidence of the fact.

The abdominal section was, therefore, from the very necessity of the case, more or less of an explor-

atory operation. That an abscess would be found was almost certain, and when the true nature of the case was revealed the gall-bladder and contained gall-stones were removed with the most gratifying result.

Monotony of detail must be forgiven in the history of this case, as the minutiæ are of more than ordinary interest.

CAUSES WHICH IMPERIL THE HEALTH OF THE AMERICAN GIRL, AND THE NECESSITY OF FEMALE HYGIENE.[1]

By GEORGE J. ENGELMANN, A.M., M.D.,
PRESIDENT OF THE SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION AND OF THE ST. LOUIS OBSTETRICAL AND GYNECOLOGICAL SOCIETY; PROFESSOR OF DISEASES OF WOMEN IN THE MISSOURI MEDICAL COLLEGE AND POST-GRADUATE SCHOOL; FELLOW OF THE AMERICAN GYNECOLOGICAL SOCIETY, OF THE BRITISH GYNECOLOGICAL SOCIETY, OF THE LONDON OBSTETRICAL SOCIETY, ETC.

To guide woman in greater safety through the dangers which beset her path in life is one of the highest and most sacred duties of our profession, as we may say that the care of woman is the care of the nation; the good health, mental, moral, and physical, of the woman and mother is the very foundation of our national growth and prosperity; and the conditions which tend to undermine that health cover a field of such extent and importance that the reader will readily realize the necessity of a limitation of my remarks.

I shall speak of the girl, the coming mother; of adolescence, the most important and interesting period of woman's life—the period of greatest functional activity, during which the foundation of future health is laid.

Girlhood is the most dangerous period, during which the organism, the budding mind, the developing system are susceptible to disturbing influences from without and within. It is the time when the clay is soft and the vessel is forming, when it yields most readily, and when trifling impressions are permanently recorded. It is in this period of school-life, the period of beginning social life, the period of learning trades, that the nervous energies of the female are most fully engaged, and her activity is concentrated on the brain-function, to the detriment of other functions, above all the developing sexual function, the central and most important, and at that time the most readily disturbed.

That I speak of the American girl is but natural, and I need hardly say that she is, moreover, subjected to a far greater number of disturbing influences than her sister in other lands, and more recklessly exposed to the very injuries which react most violently upon the female function.

[1] The President's Address to the Southern Surgical and Gynecological Association, November 11, 1890.

True as it generally is that woman is the exponent of a nation, and indicative of its development, of its growth, and of its depreciation, the American woman is more closely linked with the state and fate of her nation than the women of other countries.

Woman shares the febrile activity of our existence; she is a factor in our social and political economy; she participates in the rush and crush of the times to the utmost extent of her nerve-force and brain-power; but especially is this true of the American girl, as compared with the girls of other countries.

When I speak of the American girl I speak not of the extremes, not of the rich or the poor, but of the American girl of the great middle class of our cities—the typical American girl. Compare her to her hearty, strong-boned English sister; to the French girl raised within convent walls, carefully guarded, removed from the world until her marriage; or to the average German girl, reared amid the calmness of her surroundings, taught the solid rudiments of learning, and educated in household duties. Compare her even to her sister of the village or country, if the latter still be free from contaminating influences—from the nervous life of the city or boarding-school. You will recognize her at once. You will recognize the effect of brain-work and nerve-strain, the rush and mental activity of the day, the want of muscular training, the want of harmony in life, in training and education—mental, moral, and physical.

Whilst I will not agree with Ploss in his descriptions of the characteristics of the American girl, when he records the statements of an ungallant Yankee, that the American girl has no bones, no muscle, no vitality—only nerves; and what should we expect, he asked, when in the place of bread they eat chalk, in the place of wine they drink ice-water, when they wear tight corsets and shoes.

Even now one of our greatest authorities, and one of our keenest observers, Dr. S. Weir Mitchell, says that the American woman is unfit for her duties as a woman—not quite up to what nature asks of her as a wife and mother.

I believe that the essential causative factors to which the ill health of the American girl must be referred, are functional neglect or ignoring of her functions, excessive brain-work, and over-exertion of the nerves and emotions, with imperfect development of the muscular system, a want of harmony between development and exertion—physical, mental, and moral.

The peculiar organization of woman is too much ignored. It is claimed that woman is equal to man in her primitive state, and that her functions are physiologically and naturally not in want of any particular attention. Are these functions of such

paramount importance, and do they so completely control woman's life? This is a physiological problem upon the solution of which depend the relative capacity of woman for labor, mental and physical, and an understanding of the causes, influences, and remedies of diseases. The answer is readily found, if we observe with an unprejudiced eye the existing conditions.

Throughout both of the great kingdoms of nature the importance of the reproductive function in the female is demonstrated: it is strikingly demonstrated in the vegetable as well as in the animal life; it was recognized by the intuitive keenness of the most primitive people, and distinct expression is given to these fundamental facts in nature by the great lawgivers of ancient times.

Differences in sex are more or less well marked throughout the vegetable kingdom, and the supremacy of the reproductive function in the female, with the necessity of additional vitality for its perfect performance, is distinctly characterized. This is well exemplified in our common hemp, which, when the seed is moderately distributed over fertile soil, develops more than fifty per cent. of male plants, as a superabundance must be provided for the necessary waste which follows the distribution of the male pollen by the winds. If the seeds are thickly sown, so that the nutrition is insufficient or scant, the number of female plants will be diminished, as the supply requisite for their greater vitality is wanting; and, if densely crowded, the female plant may be altogether unable to develop. To the fruit-grower the great demand of vitality for the reproductive function is well known. The apple-tree with vigorous growth and foliage bears no fruit, its vitality being directed toward the one function of vegetable growth. To reduce this the tree is girdled, when, with a diminution of growth and foliage, it bears fruit. This harmonious development of the function is as necessary for the symmetrical growth of the plant as it is to the perfect development of the human being.

The great importance of the peculiar function of women, which it is the tendency of our enlightened nineteenth century to ignore, was fully appreciated by the people of olden times, and the necessity of functional hygiene for the welfare of the community was recognized to such an extent that it was made obligatory by laws of custom or of religion; and the highest penalties—expulsion from the community, everlasting damnation, and even death were imposed for certain transgressions which are thoughtlessly practised to-day by the refined and enlightened beings of our advanced civilization. The essence of such laws and customs of the savages of to-day, in fact of all primitive people from past to present, was rest, functional rest.

Instinct and experience have taught primitive people these truths, which in our day are but imperfectly realized even by medical science, and are denied by some who call the susceptibility of the woman of to-day to her ailments unnatural, and claim them to be altogether the result of civilization.

It is asserted that woman in her natural state is the physical equal of man, and the primitive or savage woman is constantly pointed to as an example of this supposed axiom.

Do those who make these assertions know how well the savage is aware of the weakness of woman and of her susceptibilities at certain periods of her life, and with what care he protects her from harm at these periods so that health may be retained? Religious superstition and the anger of the gods were invoked to secure this simple, but effective female hygiene—much-needed rest. Rest by isolation during the periods of functional activity, for nine days of each month, from thirty to ninety days after childbirth, and for five months at puberty. The budding of the maid into woman among savages is marked by a long period of rest and isolation, and her return to her tribe is celebrated by ceremonies of various kinds.

The importance of surrounding woman with certain precautions during the height of these great functional waves of her existence was appreciated by all people living in an approximately natural state, by all races at all times, and among their comparatively few religious customs, this one, affording rest to women, was among those most persistently adhered to. This idea was so deeply impressed that a mere touch at such periods was regarded as contaminating, and the girl was accordingly obliged to desist from all ordinary duties of life, and was removed from exertion and excitement by forced isolation. Where isolation is not customary, as we find it among people approaching civilization, a certain characteristic mark or signal is worn, for the wearer a passport of safety. In Eastern India young girls show their condition by a small piece of linen steeped in blood, and worn at the neck, as I myself have seen in the Nautch girls brought to this country for the purpose of exhibition. The Woloff negress wears a bright-colored folded cloth upon the cheek.

In the same manner the necessary rest is accorded to woman during the period of susceptibility for from three to four and even five days of each month throughout functional life. We find that either a hut is erected at some distance from the village, as among the Bedas in Cambodia, and on the isle of Yap, one of the West Caroline islands; or that a certain house is assigned as a place of seclusion within the village, as in New Caledonia, upon the coast of Guinea, and among the Kaffirs, the Hot-

tentots, and the American Indians. The Hindoos, the Nayers of Malabar, and others, assign to the woman a separate room in the house. In Japan, likewise, she is confined in a separate room, not permitted to eat with the family, and forbidden to visit even the temple, and given no possible excuse for leaving the house. Work of every kind and bathing are strictly forbidden, the dangers of cold water at this time being thoroughly appreciated by all these people, whilst it is an essential part of their religious teachings that the women should bathe before returning to their families and the village after the wave has passed. The laws of Moses and Zoroaster are almost identical, pointing to these great functional waves of woman's life as a working of the gods.

The laws of Zoroaster necessitated a seclusion of four nights for women, and, what is remarkable, she was then forced to determine her condition by examination, and if the flow had not completely ceased, indicating an abnormality, additional precautions were observed—she must remain five more nights, to which nine days were added, after which time she might cleanse herself and return to life.

The life of woman does not run smoothly like that of a man. It is characterized by marked periodicity, by ebbs and floods, by great life-waves, which are dominant in the sphere of her especial functions; waves of vascular tension and nerve excitement, marked by a heightened activity and susceptibility of her entire being, distinctly indicating that woman's periodical activity is not a local process, as we have been taught, but one involving the entire organization, as it was held to be by the ancients, and exerting a permanent influence upon that organism of whose condition and development it is indicative. The menstrual function involves the entire vascular and nervous systems, and may be said to be the central exchange of that great network of wires, the vasomotor nerves, the great sympathetic linking it most intimately with the brain and spinal cord and with every part of the system.

The most persistent period of nerve and vascular excitement is that of developing womanhood, when for months the system is in a period of unusual activity, and consequently of the highest susceptibility, which does not cease as speedily as its outward tokens disappear. Then follow the cyclical changes of mature activity, varied by the higher waves of active reproduction.

The functional wave slowly rises, accompanied with an increase of nerve activity and vascular tension, and a rise of temperature, as Mary Putman Jacobi tells us, of from 0.01° to 0.8° F., until it reaches the highest point; and it is during the decline of this wave that the depletion takes place, the distended vessels rupture and nature relieves herself, the temperature steadily falls, but does not reach the normal until after the cessation of all external symptoms.

Are we to believe that a function which so deeply implicates the entire system can be so completely disregarded? That it does not demand special care —greater care than functions less general, less susceptible, less intimately connected with the organism? Are we to believe that this function can be ignored; and are we to be guided by the dangerous arguments of those who claim that precautions are unnecessary at this period?

In considering the initial causes of disease and their effect upon woman, we must analyze not alone this one function, but we must consider the entire being of woman, in order that we may apply the proper standard, and that we may not measure her capacity for labor, mental or physical, or her powers of endurance, with those of man.

Woman—the woman of our civilization—cannot be properly compared with man; differences of many kinds exist, the most obvious of which are of course external and anatomical. Her form and shape differ; her organism is a different one; individual organs are said to be more vascular and to contain more nerves; she is more emotional, more readily exhausted, and less able to bear continuous and prolonged application; more blood is produced, and the circulation and respiration are more active. The period of puberty is shorter and more marked, and the last stages of development are reached at an earlier period of life.

Consider her lighter frame, her nervous organization, her emotional nature; consider the constant activity of the reproductive functions, the influence of this sphere which dominates her entire being; consider the intimate connection of every organ, above all the spinal cord, with this reproductive centre, and then, need we wonder that injury befalls this sensitive organization when exposed to the intense and continuous nerve- and muscle-strain of our present system of education and labor, which is upon a basis of male vigor?

Whilst the evil is great, I am happy to say that an improvement in the physique of the American girl of the better classes has become evident in late years, due to progress of the science of hygiene, and its better understanding by the educated public, and perhaps by the introduction of sound physiological and hygienic doctrines in some of the more advanced schools, but above all to the new fad, the increased popularity of outdoor sports.

In the higher classes we mark this change, and we may be thankful for the change of fashion which has produced the result. The girl must have a good color, a healthy figure, a brisk walk, to be "in

the swim"; riding and walking, lawn tennis and rowing, even fencing, have become fashionable, and are working wonders upon the health of the American girl who can afford these luxuries—the same girl who twenty years ago drank vinegar to acquire a fashionable pallor and an early grave. Compare the swinging gait of the girl of to-day with the mincing walk and the Grecian bend of some years ago.

A beginning has been made, but the greatest difficulties are still to be overcome; the American girl has a just claim to the most perfect and harmonious development, mental, moral, and physical, by virtue of the invigorating influence of an intermingling of race and blood, the favorable hygienic possibilities of her life, and the freedom she is given. But the average girl is not what she might be, and I repeat that this is due to our habits of life and our methods of labor and education.

We must of necessity inquire whether the health of the girl suffers during school-life, or, rather, whether functional life is impaired by our present methods of education, and I must unhesitatingly say that it is, unfortunately, a question which is asked in different ways and distorted by the partisans of higher education for women.

Statistics of functional health during school-life are out of the question, and we must refer to a few general facts, and to our individual observation. How commonly do we see the once healthy girl returning from school—above all from the pernicious boarding-school—neurasthenic, with flushed face, cold feet, impaired digestion, backache, and painful and disordered functions, all of which symptoms gradually fade with the enjoyment and recreation of vacation, and return with the next session of school.

It is the American idea of "putting one through" which lays the foundation of evils which not only follow the individual through life, but pursue her descendants. It is the idea of finishing her education before the pleasures of society can be anticipated. It is the source of beginning functional disturbances. She is straining every nerve for the dangerous struggle of supremacy, and, cost what it may, her ambition must be gratified; she must graduate with honor before making her *début* in society, and even now her emotional nature is excited by the foretaste of its pleasures. Evenings which should be devoted to rest are given to boy visitors and dancing parties. Healthy recreations, outdoor exercise, and the necessary sleep are neglected; school gymnastics, calisthenics, or official recreation do not afford the healthful exercise needed. An increased quantity of blood is diverted to the brain, whilst the general supply is diminished and the circulation impaired; lassitude, malaise, and local trouble follow. Is it to be wondered at that she breaks down, and that the mothers best fitted to produce capable children fail to fulfil their destiny?

In boarding-schools enervating routine takes the place of social dissipation, but the results are the same, if not worse, as the girl is removed from her natural guardian and adviser—the mother. One statement from the pen of Dr. Goodell will best indicate the frequency of the injury. He tells us that he has been repeatedly asked by physicians attending such institutions whether it were possible that laundresses could have drugged the scholars unknown to them, in order to avoid the washing of soiled napkins: so common is the complete cessation of that essential function in the most critical period of the girl's life when she is removed from home influence with a view to securing the supposed better advantages. This is the state of affairs in common schools and boarding-schools, at the most critical epoch, from the age of twelve to eighteen years.

Let us see what the results of so-called higher education are. The showing is a better one, as we may see from the report of the Association of College Alumni who have investigated the present health of female college alumni as far as practicable. The health of these girls was very much the same as that of their parents, but was three per cent. better, constitutional weakness being mostly the cause of the disorders that existed. Overwork, accidents, and bad sanitary conditions would explain others. Among the college graduates the deterioration in health is two and one-half per cent. less than in the working girls of Boston at the same time.

Worry over studies alone caused no decline in health, whilst worry over personal affairs caused deterioration of health in ten per cent. of the students, and worry over studies and personal affairs combined, in fifteen per cent., but the health of those who declined while in college has more than recovered in later years. We find but a very slight falling off, and that only from excellent to fair health, in college life, as we might expect if we consider that it is only the healthier and stronger girls who venture upon higher education, and that one-half of these avoided exertion during the menstrual period, and saw but little society. We must bear in mind that college education is an innovation of recent date, in the establishment of which modern hygiene has been consulted, and the study and recreation as well as the health of the pupil, are subject to constant medical supervision; moreover, in some of the more advanced institutions, good health is made a condition of admission, and yet Miss Howe, of the College Alumni Committee, finds that only four hundred and ninety-six out of one thousand

graduates married between the ages of fifteen and sixty, and she comes to the conclusion that the tendency of higher education for women is to celibacy. Whether this is from choice or from necessity—for reasons moral or physical—she does not say; it appears to be the natural result of misdirected culture.

The injurious effect of our present system of education upon the essential function of woman must be apparent if we bear in mind that in the period of life from twelve to eighteen, and eighteen to twenty-one years, nutrition should be directed to the essential organs of female life, whilst all other organs are in active growth, and are demanding increased supply. It is then that an increased expenditure of vital energy is demanded, and that the brain concentrates upon itself the nutrient fluid; it is at this time when the system is most susceptible to disturbing influences of all kinds, and in an almost explosive state during one week of each month, that it is subjected to the greatest strain, to excessive brain-work, nervous and emotional excitement, and even physical injuries.

Are the results not natural when we consider that girls in this dangerous period of life spend more time in study than boys, and that boys do have healthy recreation, that the Greeks even withheld male children from study until the tenth year, while laying a solid foundation for a healthy physical system and a harmonious development of the functions.

Injuries are wrought by our systems of education, and very similar are the injurious effects of our systems of labor upon the developing girl and the reproductive functions, but less obscure and more marked than those of education, for the reason that the unfortunate sufferer cannot, like the school-girl, withdraw at will, or when the evidences of injury are distinctly felt. She is obliged to continue until she is prostrated. It is not manual labor only; it is not alone wear and tear on muscle which tells—nerve-wear is still worse. The effects are seen in girls in the employments now so much affected as a so-called higher class of female labor—in telephone and telegraph offices—clerks, type-setters, and stenographers. Examples of this kind we unfortunately see every day.

A most interesting report is given by the Bureau of Labor Statistics of 1875, on the special effect of certain forms of employment on the health of women. From this I shall quote, as it is, perhaps, the first effort to regard the cardinal relation which labor bears to essential attributes of the forming woman, on which hinge all other vital results. The alarm-bell, the first evidence of coming trouble, is menstrual disturbance; and how rapidly nerve-strain reacts upon the functions we may see by the effects of an unexpected rush of business suddenly befalling a female clerk in good health, during the period of functional activity. Complete cessation of the flow, and general prostration follow, with slow and imperfect recovery.

In the main these functional disturbances are produced by over-work, with innutritious food and non-sanitary association—labor of both body and mind—the effects of disease primarily produced by early employment during animal growth, the regular and long-continued employment of the plastic, undeveloped girl, and the long day's work with unremitting attention. As causative errors in the management of mental or manual labor are mentioned in this most admirable report the following:

1. *a.* Youth unequal to the work.
   b. Impairment of animal growth.
   c. A constrained position.
2. *a.* A disregard of ultimate injuries.
   b. Unbroken application without vacation for a long term.
   c. Depression and disease inviting demands on immature vitality.
3. Employment in unsuitable occupation for condition of body and mind.
4. *a.* Unduly long hours.
   b. Concentration of vital energies, involving extreme nerve-tension.
   c. Unfavorable sanitary surroundings.

Constant injury is wrought by the error of system in schoolroom and workshop, but potent and more directly evident causes of ill health and functional disturbance in the growing girl exist in our daily life, our social customs, and our habits of dress. To them I will not refer; they are too well known.

The constriction and compression of the corset, the dragging weight of the skirt, the circulation-impeding garter, the insufficient covering of low-necked dresses, and of thin stockings and shoes, the total absence of protection where it is most needed, and the absence of drawers.

Among our social customs there are many which bring ruin to woman. I cannot even touch upon them all; there is but one of which I shall speak, and that is the most dangerous of all, more or less underlying all other causes of disease; it is the ignoring of the function of woman by woman—the mother's ignorance of its import. Fearful are the consequences of woman's ignorance, the calamities which follow the course of the misguided mother, swift, certain, and lasting the penalties inflicted upon the unadvised or ill-advised girl, whose one great misfortune is ignorance. She steps into the unknown sphere of womanhood, and in darkness she pursues its irregular path; and fortunate is she who by chance does not stumble.

Many who might be saved by proper manage-

ment during the transition from adolescence to maturity, now fall victims to their ignorance, and no words of mine could be more convincing than the data given by Tilt as far back as 1853, in his admirable work on the *Elements of Health and the Principle of Female Hygiene*, which shows how many are injured by the unexpected appearance of the unknown function.

Great is the danger in all classes, be it from ignorance or modesty, and most susceptible is the highly-strung nervous system of refined organization. Even though the bark float in safety through that first stormy epoch of life, it is constantly endangered, most of all from the ceaseless crash of the ever-recurring waves of functional activity, and it remains in need of guidance until it has passed through a final storm into calmer waters. The mother is the pilot, and functional hygiene the guiding chart, and the physician the engineer who maps it out.

I cannot exaggerate the danger to the health of the susceptible girl, from each wave of functional activity. The greatest danger is during the height of the wave—that period of greatest activity throughout the entire system, the period of vascular pressure and nerve excitement, which threatens her functions as well as does the era marked by local depletion and depression, the decline of the wave.

So common are the injuries to the health of woman at this epoch, that I need state but a few of the examples which have come under observation during the writing of this paper,—in fact, I may say, almost upon this very day. Fright, nervous and emotional excitement, and exposure to cold have brought injury to many at this time. What is more natural than that the anxious girl should seek to check the bleeding wound, as she supposes? For this purpose the use of cold washes and applications is common, and some even seek to stop the flow by a cold bath, as was done by a now careful mother, who lay long at the point of death from the result of such indiscretion, and slowly by years of care, regained her health. The terrible warning has not been lost, and mindful of her own experience she has taught her children a lesson which but few are fortunate enough to learn.

How many, passing in safety through the first ordeal, are ruined by an indiscretion, or an exposure at a later period. Many a vigorous frame has been broken, health has been ruined, and death even caused, by disturbance of the function during its period of activity, by exposure, by cold, by physical or mental exertion, by nerve or emotional excitement. A cold foot-bath during the period, a dance in a low-neck dress, a walk in rain or snow, a hard day's work of mind or muscle, and excitement of heart or head has made an invalid of many a previously healthy girl, by its influence on this omnipotent function.

CONCLUSION.—I have endeavored to show that the health of the American girl is threatened and impaired by causes more or less avoidable, as they are due to our methods of life, of training, and of education; that the physique of this girl, who is most favorably situated, is imperfect; that her brain is overworked, her nerve power exhausted, her function impaired, and reproduction endangered; all by reason of the susceptibility of her peculiar organization, and the increased impressionability of the sensitive system during the years of development, in which it is subjected to the most severe strain.

Such is the fact: What is the remedy? Condition and cause make the remedy self-evident. Let me briefly review the conditions as we have found them. A perfectly-organized being, in the very beginning of woman's existence, waning with the rise of the great wave of functional life during the period of functional development; showing nerve and physical prostration, with impaired circulation and digestion, imperfect menstruation, and diminished reproductive power; neurasthenia and functional disturbances constantly intermingled as cause and effect. These unfortunate results are brought about, in the main, by more or less similar influences, viz.: 1. Excessive brain-work and nerve-strain, with neglect of the physical system in education. 2. Nerve-strain and partial or incomplete muscular activity in labor; both influences which are inseparably connected with, and complicated by, independently potent causes. 3. Ignoring and neglecting functional hygiene. 4. The physical and emotional strain of society, and the improprieties of dress and over-stimulation of the senses.

The remedy is attention to woman's peculiar organization and to the cyclical waves of her dominant function; or, in other words, harmonious development and occupation of nerve and muscle; diminished brain-work and nerve-stimulation with increased and coördinate physical exercise; increased protection and diminished compression of dress; and self-knowledge and individual care during periods of heightened susceptibility. Changes are necessary in custom and fashion, in methods of labor and education. Whilst each individual, and each calling, is a law unto itself, I may say, in a general way, that we should endeavor to obtain the end of education in its widest senses, the development of all functions and faculties, to render the girl in every way fit for the life she is to enter—"to render youth beautiful, healthful, strong, and honest."

An approximately harmonious co-education of mind and body should be reached with coincident

maintenance of proper hygienic conditions. The nerve and emotional strain of class competition must be abolished; the stress of constant work, the train of thought and the routine of regulation must be broken; lungs and heart should be educated, rather than memory; the nerve-strain varied by healthful pleasure and physical exercise in the open air, and relieved more or less, according to individual necessities, during periods of heightened susceptibility.

Whilst the initial causes of ill-health in the schoolgirl may be readily overcome, the dangers which beset the laboring girl, though equally evident, are more difficult to remove. The same necessity exists for individual care, upon the height of the functional wave and during its period of decline; and the same necessity for a proper coördination of labor, physical and mental. There is the same danger from constant application, from the strain of one part, one function or organ, to the exclusion of others. Nerve-tension is even more continuous and intense, and muscular exertion limited to individual muscles. The years of development should be respected and the continuity of labor broken, and rest and change afforded frequently for short periods. Much good might be done by changes in dress, and last, but not least, by self-knowledge.

I will close with a plea for the self-care of the girl, and for her proper physiological instruction by the mother, which alone will mitigate or remove the initial cause of many of her ailments. I wish to impress upon the mother that the perfect development of the female function, and the maintenance of this function, once developed, in a healthy condition, are essential to the perfect development of the girl and the perfect health of the woman; that self-care and well-regulated hygiene form the foundation of her well-being, and that it is the mother's first duty so to guard herself and so guard her daughter.

MEDICAL PROGRESS.

The Treatment of Boils.—Veiel (*Monatshefte für praktische Dermatologie*, Oct. 15, 1890) admits that we already have efficient antiseptic means for the treatment of furuncle, such as Biddle's method of injecting with a hypodermic syringe three-per-cent. carbolic acid solution, Lewin's method of cauterizing with nitrate of silver, and the application of Unna's sublimate paste; but he thinks that these methods are too painful for general use, particularly when more than one boil is present. In the place of these the author uses a paste composed of equal parts of zinc oxide and vaseline, and four per cent. of boric acid. The ointment is thoroughly rubbed into the skin around the boil three times daily, and is also thickly spread upon lint and applied. In cases of general furunculosis the whole body is rubbed with the ointment.

Treatment of Cholera Infantum.—Dr. Leonard G. Broughton, of, Reidsville, N. C., recommends the following mixture in severe cases of cholera infantum with profuse and watery stools:

R.—Salicylate of bismuth	. .	2 drachms.
Sulpho-carbolate of zinc	. .	4 grains.
Chalk mixture	. . .	1 ounce.
Paregoric } of each	. .	½ " .—M.
Water }		

One drachm of this should be given every two hours until the bowels are controlled, after which the following is prescribed:

R.—Calomel	. . . . . 1 grain.
Sulpho-carbolate of sodium	. . 20 grains.
Saccharated pepsin (P. D. & Co.)	. 10 "

Divide in ten powders and give one every three hours. If the stomach is not irritable, sulpho-carbolate of zinc is substituted for the sodium salt in the last prescription. —*Therapeutic Gazette*, November 15, 1890.

Treatment of Hæmorrhoids by Cold Water.—According to *La Semaine Médicale*, Dr. Alvin employs very cold water for the pain, tenesmus, and spasm of the sphincter ani muscle provoked by congested hæmorrhoids. The water is applied to the anal region by means of a sponge. This method is very successful when continued for a number of days, and as a result the growths decrease in size, and there is general relief from all the unpleasant symptoms. These results are practically identical with those obtained by Dr. J. William White, of Philadelphia, whose paper appeared in The Medical News some months ago.

An Efficient Method of Removing Foreign Bodies from the Nose.—Dr. S. Johnson Taylor (*Lancet*, November 8, 1890) describes the following method of removing foreign bodies from the nose, which was successful in the case of a child of three years with a large bead in the nostril. The procedure is simply Politzer's method of inflation through the unobstructed nostril:

The nozzle of the Politzer bag is introduced into the nostril which does not contain the foreign body, and if the patient is old enough he is requested to swallow a mouthful of water. During the act of swallowing the bag is vigorously compressed, the escape of air from around the nozzle being prevented by grasping the nose with the thumb and forefinger. At the moment of compressing the bag the foreign body will probably be blown out. In the case of a young infant the compression should be made while the child is crying.

The Treatment of Enlargement of the Spleen.—Mosler (*Wiener medicinisch· Wochenschrift*) writes that all enlargements of the spleen, irrespective of their nature, size, and duration, are frequently associated with a hæmorrhagic diathesis, which may not have become apparent. For this reason he disapproves of any operative procedure for the removal of the organ, and for some time has used a variety of other measures, chiefly injections, to reduce the swelling. He at first tried parenchymatous injections, by means of a syringe with a long needle, of weak carbolic acid solution. Later he in-

jected pure Fowler's solution with better results—decrease in the size of the organ. Injections of iodine and of quinine he considers dangerous and he has not tried, nor does he approve of the injection of ergot and its preparations. He believes that the cases suitable for injection are those in which the spleen is hard and not associated with extreme anæmia. Fowler's solution, he thinks, is better than the numerous other drugs which have been recommended for the purpose. The dangers of the injection are diminished by applying an ice-bag to the splenic region for an hour or two before and after the operation. — *Centralblatt für Chirurgie*, October 11, 1890.

The Use of Small Doses of Antifebrin.—In the treatment of fevers which are accompanied with cyanosis and collapse, Professor Sahli, of Berne, employs minute doses of antifebrin, believing that the effect on the temperature can be thus obtained without the disagreeable symptoms attending the administration of large doses of quinine. Antifebrin acts rapidly and effectively in small quantities; on the contrary, quinine has no action on the febrile state when administered in minute doses, and may produce untoward effects from its accumulation in the system. Sahli's observations, comprising eleven cases, have been collected by Favrat in a recent work, and show that antifebrin in small doses is very efficient in combating fevers. The drug was given in doses of from 5 to 10 centigrammes in the form of pilules. Cases of pulmonary phthisis and of typhoid fever were decidedly influenced by antifebrin, and while the drug reduced the temperature, it produced at the same time a sensation of comfort. It prevented sudden exacerbations, and only in two cases were untoward effects noticed, such as cyanosis, but vomiting and digestive troubles were never observed. The same good results were obtained in the treatment of typhoid fever. In young children the initial dose should not exceed two centigrammes. The drug, of course, does not influence complications, and in phthisis, for example, neither the progress of the disease nor the cough is prevented. It is the fever alone that antifebrin attacks, and thus prepares the organism, as it were, to resist more successfully the other symptoms of the disease. The higher the temperature the more decided is the action of antifebrin. It was observed that a temperature of 39° C. could be reduced 1.9° C. by a dose of 10 centigrammes. In the period of decline the drug appeared to exercise the same action, but less markedly.—*La Médecine Moderne*, September 25, 1890.

Injection for Seat-worms.—The *Annales of Gynæcology and Pædiatry* quotes the following prescription to remove seat-worms:

℞.—Tincture of rhubarb	. . .	30 drops.
Carbonate of magnesium	. .	3 grains.
Tincture of ginger	. . .	1 drop.
Water	. . . . .	4 ounces.

The mixture should be warmed and used as an injection, repeating three or four times in twenty-four hours.

A Simple Method of Estimating Fat and Casein in Milk.—Dr. J. B. Nias (*Lancet*, November 15, 1890) has devised the following convenient method of estimating the fat and casein in milk in connection with the feeding of infants:

Place some of the milk in a test-tube with a piece of red litmus-paper, add a drop or two of liquor potassæ—enough to render the milk distinctly alkaline as shown by blueing of the litmus paper—and boil. Set aside in a warm place, when the fat will rise to the top, a small but constant percentage remaining behind. The proportions can be determined by a graduated rule placed at the side of the tube. Remove the layer of fat with a small glass pipette, add sufficient acetic acid to redden the litmus-paper, boil, and set aside in a warm place. The whole of the proteids will be precipitated and the relative proportion can again be determined by the graduated rule.

Albuminuria in Children.—Dr. Seyournet (*L'Union Médicale du Nord-Est*) describes a form of albuminuria in children which he thinks is not infrequent. It differs from scarlatinal albuminuria. He has studied the disease in children between the ages of eleven and sixteen months. Many of the patients were bottle-fed and had been given improper food, which caused distention of the stomach, intestinal catarrh with vomiting and diarrhœa, or in a few instances enlargement of the liver. The author believes that the albuminuria is toxic and due to certain substances generated by abnormal fermentation in the intestines, the absorption of these substances causing congestion or inflammation of the kidneys. The disease was usually accompanied with anuria, and in some cases the daily amount of urine did not exceed one-half ounce. A marked symptom was œdema of the feet, occasionally extending to the eyelids and face. The duration of the disease was two to four weeks. The treatment consisted in the administration of milk to which lime-water was sometimes added; salicylate of bismuth to disinfect the intestines; gentle aperients when there was vomiting, and systematic massage of the lumbar region in order to reduce the congestion of the kidneys.—*Lancet*, November 15, 1890.

Injection for Cancer of the Bladder.—

℞.—Iodoform, Glycerin	of each . .	1 ounce.
Distilled water	. . .	1 drachm.
Gum tragacanth	. . .	2 grains.—M.

Add a teaspoonful of this mixture to a pint of hot water. The bladder is first to be washed out with water as hot as can be borne, after which the iodoform mixture just named may be injected, and then permitted to escape. These injections should be repeated three times a day; and it is worthy of remark that after three or four injections very great relief generally ensues.

Prescription for the Prevention of Dental Caries.—

℞.—Tannic acid	. . .	75 grains.
Tincture of iodine	. .	1 drachm.
Tincture of myrrh	. .	1 "
Iodide of potassium	.	15 grains.
Rose-water	. . .	6 ounces.—M.

Make into a solution and use a teaspoonful in a wineglassful of hot water as a mouth-wash.

PYOKTANIN IN DISEASES OF THE EYE.

ALTHOUGH a mass of clinical and experimental evidence in regard to the antiseptic and therapeutic qualities of pyoktanin has been published since its introduction by Stilling, we are by no means in a position to know the exact value of the drug. We are confronted on the one hand by the claims of the discoverer that pyoktanin is devoid of injurious effects upon the animal economy, that it is destructive to microörganisms, and that it is rapidly diffusible in healthy and in diseased animal tissues; and on the other by those who not only have failed to obtain the usual results from its use, but warn against its indiscriminate employment. The many diseases of the external coats of the eye and its appendages, probably largely dependent upon microbic infection, should afford an excellent field for studying the effects of this new claimant for antiseptic and therapeutic favor. Here we are at once met by discordant views. Stilling, as we all know, reported rapid cure of blepharitis, eczema of the lids, conjunctivitis—simple and phlyctenular—corneal ulcer, marginal and parenchymatous keratitis, serous iritis, and even disseminated choroiditis. Bayer, after its use in forty-six cases of scrofulous pannus, various types of corneal ulcer, dacryocystitis, parenchymatous keratitis, iritis, and sympathetic iridocystitis, came to the conclusion that the excellent qualities attributed by Stilling to this aniline dye did not exist in fact; and, moreover, in addition to disagreeable discolorations, positively harmful results might follow its application.

Quite recently some very careful clinical observations have appeared on this side of the water. Thus Dr. G. M. Gould (*University Medical Magazine*, December, 1890) reports his results in the eye wards of the Philadelphia Hospital, results which are particularly valuable, because this observer, wherever possible, treated one affected eye with pyoktanin, and the other with either nitrate of silver or bichloride of mercury. In trachoma the drug was without noticeable effect, and in some instances, owing to a species of desiccating effect, injurious. In gonorrhœal ophthalmia nitrate of silver was the preferable drug, and in corneal ulcerations other substances, especially eserine, produced far better results. In dacryocystitis, lachrymal conjunctivitis, unhealthy orbital cavities, and chronic soft leucomata, the sequelæ of interstitial keratitis, pannus, and like affections, pyoktanin did excellent service. Dr. Gould is particularly strong in his praise of the efficacy of the drug in chronically unhealthy conditions of the lachrymal excreting apparatus. Dr. W. Cheatham (*The Cincinnati Lancet-Clinic*, November 15, 1890) observed numbers of cases of the milder conjunctival affections readily yield to solutions of pyoktanin, and instances of trachoma, unaffected by the usual remedies, showed remarkable changes for the better under the daily application of the pyoktanin pencil. Cheatham and Gould are in accord that the remedy is of unusual service in muco-purulent inflammation of the tear-sac.

It will be remembered that Stilling states that pyoktanin dilates the pupil. One of Cheatham's cases affords an interesting confirmation of this fact—an example of interstitial keratitis in which atropine failed to produce its physiological effect upon the pupil, but when it was employed in conjunction with pyoktanin the desired mydriasis was secured.

We have used pyoktanin quite freely, and are in entire accord with those observers who find it of excellent service in diseases of the lachrymal passages, and believe that we have never obtained equal results with any other drug. It is a good application in the various types of inflammation of the conjunctiva associated with the formation of pus, but not better than several other standard remedies. We have failed to observe any curative effect in other diseases of the eye.

Pyoktanin may be prescribed either in the form of the blue or the yellow variety, and used in a solution, as a pencil, or in powder. Solutions are most desirable in acute conjunctivitis, dacryocystitis, etc., but in chronic ophthalmia, trachoma, and old fistulous openings into the lachrymal sac, the direct application of the pencil would seem preferable. The intense discoloration which blue pyoktanin produces is an objection, but the stains may be removed from the skin by scrubbing them with alcohol and water.

KOCH'S DISCOVERY.

The dispatches which are being constantly received from Berlin tell us nothing of importance in regard to the emyloyment of Koch's remedy for tuberculosis, and time has not elapsed in which to determine the value of the treatment. No one beyond the boundary-line of Germany has as yet received any of the lymph, except Dr. Watson Cheyne, of London, and one or two Viennese physicians. The introduction of a quantity of it into France, sent to Pasteur by Koch, was prohibited on the ground that it was a medicinal agent of unknown composition.

In other columns will be found accounts of various cases treated by von Bergmann, Levy, Fräntzel, and Gerhardt which are of great interest.

We are glad to announce that of the first three American physicians to register in Berlin, our special correspondent, Dr. John Guitéras, the Professor of Pathology in the University of Pennsylvania, is one, that Dr. Dixon, representing the Jefferson Medical College, is the other, while Dr. Herring, of New York, is the third.

Dr. Guitéras goes to Berlin prepared to keep our readers fully informed of Koch's work and its results by letter and cable.

CORRESPONDENCE.

ATLANTA.

To the Editor of The Medical News,

Sir: The Southern Surgical and Gynecological Association, which recently met here, was a great success, and, in the language of Dr. Hunter McGuire, "the Association came into the world a lusty infant, and its cry was heard all over the South." The papers read and the discussions would have done credit to any medical body. The officers have been uniformly efficient. Dr. Hunter McGuire, who was the first President of the Association, has an international reputation as a surgeon. The Secretary of the Association—in fact, almost the organizer of it, Dr. W. E. B. Davis, of Birmingham, Alabama, is one of the most tireless and enthusiastic workers in America. He is a man of high literary attainments and great personal magnetism, and he has linked with his magnetism an unsurpassed energy.

Perhaps no man was better fitted to occupy the executive chair than the retiring President, Dr. George J. Engelmann, of St. Louis. Dr. Engelmann was born in St. Louis in 1847. He was graduated from Washington University, and from that college received the degree of Master of Arts. To obtain his medical education he studied for six years in Europe. He is a graduate of the Berlin University, from which he received the degree of Doctor of Medicine. He is also a graduate of the Vienna University, which conferred upon him the degree of Master of Obstetrics. During the greater part of the Franco-Prussian war he served before Metz, in the hospitals of Lyons, and in the reserve hospitals in the University of Berlin. At the close of the war he returned to this country, resuming the practice of medicine in his native city in 1873, and has since been connected in various capacities with the medical colleges there. He is now Professor of Gynecology in the Missouri Medical College, President of the St. Louis Obstetrical and Gynecological Societies, and was Honorary President of the Gynecological Section of the International Medical Congress, which met at Copenhagen. Dr. Engelmann commenced practice as a general practitioner, but gradually drifted into gynecological work. Finding his work in this direction assuming gigantic proportions, he abandoned his general practice, and has since devoted his entire attention to obstetrics and diseases of women.

His successor as President of the Southern Surgical and Gynecological Association, Dr. L. S. McMurtry, is a native of Kentucky and a graduate of Centre College of that State. He was graduated in medicine by the University of Louisiana, and afterward studied at the University of the City of New York. He was Professor of Anatomy in the Kentucky School of Medicine for several years, and is now Surgeon to the Saints Mary and Elizabeth Hospital of Louisville. Two years ago he was President of the Kentucky State Medical Society. Dr. McMurtry has made numerous contributions to medical literature, chiefly relating to abdominal surgery and the diseases of women. He is a Fellow of the Obstetrical Society of Edinburgh, and is about thirty-eight years of age.

The Association is now in the third year of its existence, it having been organized in Birmingham, Alabama, in 1887. It has been successful from its inception, and is steadily increasing in membership, which will be limited to one hundred. It is a Southern organization, but it is not sectional in the *political* meaning of the word. It will take in all good men, whether from the North or South. But the intention of its organizers was that all its meetings should be held in the South. The North has its organizations, from which Southern men have in the past been practically frozen out, and they have been unable to obtain the benefit of an interchange of views and mutual discussions of important medical and surgical questions.

Dr. Engelmann tendered a lunch to the members of the Association, while the Capital City Club held a reception and tendered the Association a banquet, which

was one of the most elaborate affairs of its kind ever given in Atlanta.

Many visiting members of the Association were entertained by resident members.

Dr. Hunter P. Cooper has just been appointed surgeon for the Georgia Railroad, and will enter upon the discharge of his duties at once. He is one of Atlanta's most successful and popular physicians, and thoroughly worthy of the position.

CHICAGO.

To the Editor of THE MEDICAL NEWS,

SIR: A small pamphlet of one hundred and thirty-seven pages has just been published by Mr. James C. Strain, Ex-warden of the Cook County Hospital, and is entitled *Medical and Surgical Reports of the Cook County Hospital, Chicago, for the six months ending July 1, 1890.* It includes a history of the hospital and the registrar's report, the surgical and medical abstracts being well illustrated. It is the first medical report of the hospital that has been issued. The Cook County Hospital is just twenty-five years old, having been organized in 1865, though it did not begin its work until January, 1866. Previously to that time the city cared for its sick at the Mercy Hospital. But in January, 1866, it fitted up two wards in the old City Hospital, at the corner of Eighteenth and Arnold Streets, and moved to them twelve patients from the Mercy Hospital. These wards were rapidly filled, and additions to the building were erected. But these, too, soon became overcrowded, and in 1876 the institution was removed to its present location, at the corner of West Harrison and Wood Streets. The new structures, not all of which were erected at the same time, consist of a long administration building of imposing appearance, and a pavilion of four wards with a wing of three wards on each side. There is plenty of space between all these buildings, conducing not only to their appearance, but to the light, ventilation, and comfort of the wards. The grounds contain twelve acres. In the administration building are the main office, the examining room for patients, the drug store, the office of the custodian, the office for coroner's inquests, the offices of the warden, the registrar, the chief clerk, the hospital committee, and the medical board, and the private apartments of the warden, internes, and druggist. In the rear of this building are the instrument-room, the office of the training-school for nurses, and the amphitheatre.

The wards are thirteen in number, and of these, three are men's medical wards, five are men's surgical wards, one is a woman's medical ward, and two are women's surgical wards, one is an obstetrical ward and one a ward for children. The pavilion wards are large, being 120 feet long and 30 feet wide. There are in each of them about forty beds. The wing wards are 40 feet long and 15 feet wide, and contain about thirty beds. They are lighted by windows on three sides, and each ward has in connection with it a bath-room, a nurse-room, a linen-room, a kitchen, and a dining-room. The surgical wards have, in addition, operating-rooms. The beds are iron, with woven-wire springs. The floors of the wards are of Georgia pine, and the floors of the corridors are paved with tiles.

During the six months ending January 4, 1889, there were received and treated 3255 cases, and during the six months ending July 1, 1889, 3903 cases, showing an increase of 648. As there were 435 patients present on January 1, 1889, and 488 on July 1, 1889, the number in the hospital during the two periods, respectively was 3690 and 4391. So that it is only a matter of time when the vast accommodations of the hospital will have to be increased to keep pace with the growing wants of our city.

The September grand jury of Chicago, after visiting the public institutions, recommended that a crematory be built at the Hospital, and that some of the inmates of the infirmary should be sent to the State institution.

The registrar's report contains analytical tables of the diseases treated, of the patients admitted, of the conditions in which some of them were discharged, and of the number of those that died. This report is followed by a long and interesting dissertation on the "Treatment of Empyæma," by Dr. Bayard Holmes, editor of the *North American Practitioner*.

The surgical abstract includes cases of compound fracture, bullet wounds of the hand, injury of the musculo-spiral nerve, fracture of the larynx from falls, death from œdema of the glottis, fracture of the trachea, resection of the ulnar nerve, nephrorraphy, and many other interesting subjects. The medical abstract contains many interesting cases, including carcinoma of the œsophagus, rupture of the portal vein from a fall, chylous ascites, Hodgkin's disease, thoracic aneurism, Landry's paralysis, etc.

Dr. William N. Hibbard, of this city, died on October 29th. The cause of his death is said to have been ptomaïne-poisoning, and the attendant circumstances were peculiarly distressing.

About a week before his death Dr. Hibbard ate some oysters, which, doubtless, contained the poisonous substance. The paroxysmal efforts of his digestive system to rid itself of the poison brought on intussusception, and his physicians decided that his life could be saved only by an operation. The patient, however, was too weak to rally, and died while under the influence of the anæsthetic.

Dr. Hibbard was born December 16, 1858, at Freeport, Illinois. He was prepared for college in the Hyde Park High School, and entered the University of Vermont at Burlington, of which both his father and grandfather were graduates. He was graduated in the class of 1880. He taught for three years in the High Schools of Chicago and then entered the Chicago Medical College, from which he was graduated in 1886. He was then appointed an interne in the Cook County Hospital, serving for eighteen months, after which he began the practice of medicine in Hyde Park, and was shortly after appointed Demonstrator of Anatomy in the Chicago Medical College. Few young physicians had brighter prospects, or a larger number of friends. After his graduation from the Chicago Medical College he married Miss Mary Barker, of Kenwood, who, with a son two years old, survives him.

At a recent meeting of the Chicago Medico-legal Society, Dr. M. H. Lackersteen read a paper entitled "The Scientific Aspect of Medical Hypnotism." He asserted that of all modern therapeutic measures hypnotism

has caused the most debate and excited the most prejudice. He believed that the dreams of hypnotism are no more dangerous or injurious than are those of normal sleep, and denied that hypnotism leads to mental derangement or to paralysis. There are few remedies, he said, that are not dangerous when carelessly used, and this is also true of hypnotism. The fact that ignorant persons can exercise the hypnotic influence is no argument against the usefulness of hypnotism. He regretted that quacks and impostors have taken advantage of the new discovery and brought it into disrepute. There are few people, he said, that are not susceptible to the hypnotic influence, and some can be influenced even by a letter. A case was cited in which a physician frequently wrote to a certain patient telling him to fall asleep at a certain hour. The order was never disobeyed.

During many years of life in India, Dr. Lackersteen had an opportunity to witness the results of hypnotic treatment as practised by Indian doctors. They accomplished by charms, incantations, and superstitions, cures which would baffle the most skilled, scientific physicians.

DR. GOODELL'S ARTICLE.

To the Editor of The Medical News,

Sir: In your issue of last week, my article entitled "What I have Learned to Unlearn in Gynecology" contains a serious error, which was overlooked in the proof-reading. In the first column of page 562 the word *not* should be erased, and the sentence should read: "I have learned to unlearn the idea—and this was the hardest task of all—that uterine symptoms are always present in cases of uterine disease; or that, when present, they necessarily come from the uterine disease."

Yours truly,
William Goodell, M.D.

NEWS ITEMS.

Koch's Method.—The special correspondent of the *British Medical Journal* gives the following account of von Bergmann's, Levy's, Fräntzel's, and Gerhardt's cases:

Dr. v. Bergmann's anxiously-expected address and exhibition of cases treated by Professor Koch's method took place on Sunday evening, November 16th, before a numerous and select audience of invited guests. The Minister of Public Instruction, Herr von Gossler, and amongst other celebrities Professors Virchow, Gerhardt, Liebreich, Waldeyer, and Olshausen were present. In beginning his address Professor v. Bergmann referred in stirring words to the intense emotion which, since Koch's publication, had seized not only suffering but also healing humanity. He then discussed the cases that had come under his own observation, which were cases of (1) lupus, (2) glandular tuberculosis, (3) tuberculosis of the joints and bones, and (4) tuberculosis of the larynx. Five lupus patients were exhibited, to whom a subcutaneous injection of one centigramme of Koch's remedy had been given in the morning between 8.30 and 9.30; all these five cases showed the general and local symptoms spoken of by Koch—namely, fever and inflammation. The lecturer remarked that the unerring certainty with which an attack of fever, accompanied by rigors, followed the application of the remedy, was of the highest interest from a medical point of view. This general reaction was invariably accompanied by a marked action on all tuberculous parts of the body—visible in cases of lupus. Of the patients exhibited some showed temperatures of 41.0° C., and even higher. The lupus spots were enormously swollen and very red, this reaction being more marked in recent cases. One of the patients had suffered from the disease for twenty years and one for twenty-nine years. On Sunday morning, before the subcutaneous injection was given, Professor Gerhardt had designated the first of these as a slight and superficial one; nevertheless, an enormous reaction followed the injection, tending to prove that there was more lupus than had yet been found, and that Koch's remedy finds the most secret places and nests of tubercle bacilli.

The next five patients exhibited were treated in presence of the assembly by Stabsarzt Dr. Pfuhl, subcutaneous injections in varying doses being applied to the back. One of the patients was a sickly-looking lad of seventeen, who had been under Professor v. Bergmann's and the late Professor Volkmann's treatment for the last fourteen years. "Now the poor fellow will have relief at last," said Professor v. Bergmann, smiling.

The next set of three patients exhibited had been under treatment for some time, and had gone through a course of subcutaneous injections, the reactions becoming weaker after each injection. Here partial cure was already visible; but the application will be continued until no reaction at all can be observed.

Professor v. Bergmann resumed his address by remarking that the value of the remedy was enhanced by the control experiments that could be made in the case of healthy subjects, or those affected by other diseases, which were all-important for diagnosis. He illustrated this by exhibiting a patient suffering from an affection of the cheek, which might have been considered tuberculous. The experimental subcutaneous injection produced no feverish reaction. Probably this case was syphilitic.

The second group exhibited contained two cases of glandular tubercle, in the person of two little girls of scrofulous appearance. Here the reaction was marked.

The third group comprised sixteen cases of tubercle of the joints and bones, with suppuration, fistulæ, and similar phenomena. Some of these, to whom a first injection had been applied, showed the usual symptoms; the joints were much swollen and highly colored, and movement was scarcely possible. Others had been treated by repeated injections. One of these, who suffered from consumption and tuberculous inflammation of the knee-joint, was so severely affected by the injections (intermittent pulse, faintness, etc.), that there seemed cause for anxiety. He had, however, recovered, and was progressing favorably.

The last patients exhibited excited special interest, as they were cases of tubercle of the larynx. Professors Gerhardt and von Ziemssen had in both cases found serious lesions of the larynx. And here the remedy showed its diagnostic value as a means of distinguishing cancer from tuberculosis.

In summing up the cases exhibited, Professor v. Bergmann said that from the local and general phenomena which had already shown themselves the prognosis was decidedly favorable. Nevertheless, in many cases surgical operations would still be unavoidable, as abscesses and dislocations could be cured by mechanical means only. In these cases it would be of the highest importance to guard against relapse by the repetition of Koch's treatment, and thus both methods united gave the brightest prospect of success.

The *Therapeutische Monatshefte* publishes a supplement containing an account of cases treated by Koch's new method in Dr. Levy's clinic. The report, written by Dr. H. Fielchenfeld, Levy's assistant, is here summarized: The treatment was begun on September 22d, that is, not quite two months ago. This comparatively short time has sufficed to show in what cases complete recovery may be hoped for, and where only amelioration of symptoms can be expected. No definite opinion can be formed as to the length of time necessary for perfect recovery. Fielchenfeld cites three cases of lupus, one of which is a sort of test-case, and has already become celebrated in the history of the investigation. In this case all the phenomena of reaction took place in the typical form with which Koch's paper has made the world familiar. A complete cure seemed to have been effected—it was as though the diseased tissue had been cut away with a chisel. Further subcutaneous injections, however, proved that the end of the trouble had not been reached, and that in spite of superficial cicatrization there was considerable tuberculous tissue below awaiting destruction. Even now the patient cannot be considered cured. In a second case of lupus the general condition of the patient became much worse after each subcutaneous injection, and severe pains persisted, especially in the bones of the affected arm.

A third case of lupus is interesting because, of all cases treated in Levy's clinic, it is the one furthest advanced toward recovery. In this case the subcutaneous injections no longer produce a reaction. Here too, however, Dr. Fielchenfeld speaks of "provisional cure" only, as no final verdict can be given after two months in a disease which runs its course so slowly as tuberculosis does.

In cases of tuberculosis of the bones and joints, cures were effected; that is, no reaction followed the subcutaneous injection of even large doses. The same result was obtained in cases of glandular tuberculosis. Turning to his cases of consumption, Dr. Fielchenfeld states that three patients in the first stage of phthisis were dismissed as cured, their sputum having been found free from bacilli, and the auscultatory signs having considerably decreased. Dr. Fielchenfeld, however, does not consider these two facts a complete proof of definite cure. Bacilli may disappear from the sputum to reappear after a time.

As regards the more advanced forms of phthisis, where cavities have already formed, Dr. Fielchenfeld remarks that no complete recovery has been observed. But the general symptoms of the disease—night-sweats, etc.—disappeared promptly. Even in the worst cases there was a diminution of expectoration. There was no increase of weight, even when the general condition was much improved. On the other hand, no loss of weight was observed, even in the most advanced and desperate cases.

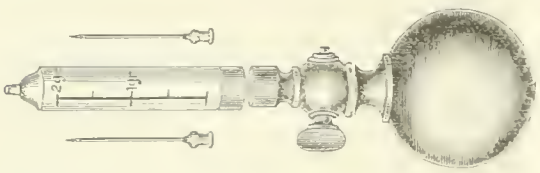
At Monday's meeting of the Verein für innere Medicin, Professor Fräntzel gave an account of the cases treated in his clinic by Koch's method. He divided them into two classes: (1) those in the first stage of phthisis; (2) those in advanced stages of the disease (disintegration of tissue, cavities, etc.). In the latter group no change of condition could be observed. Two patients died during treatment; their cases were desperate from the beginning. The *post-mortem* examination showed no indication of the commencement of recovery. Fräntzel utters a word of warning against using large doses at the beginning of treatment in advanced cases, and cited one case in which death ensued after twenty-four hours. As regards the first group of patients—early stages of consumption—Professor Fräntzel was able to record decided improvement. Expectoration was easier and more abundant after the injection, while the cough decreased. The general condition visibly improved; the appetite became keener, the weight increased, and the night-sweats disappeared. The microscopic examination of the sputum demonstrated first a decrease, and secondly a change of the bacilli. They seemed stunted; nevertheless, their vitality was not destroyed. Fräntzel is of opinion that the treatment, even in the most successful cases, must be continued for a considerable time to guard against relapse.

In a clinical lecture given in the presence of many distinguished physicians on Tuesday, November 18th, Professor Gerhardt gave an account of his experiences with Koch's remedy. He exhibited three cases specially fitted to illustrate the progress made in the diagnosis and treatment of tuberculosis. The first case was one of tuberculosis of the throat, in which various methods had been tried without effect. On Sunday, two milligrammes of Koch's fluid were injected, and a decided reaction was observed on Monday. Considering the success which has attended a similar case in v. Bergmann's clinic, Professor Gerhardt thinks that recovery is possible. The second case was in the initial stage of consumption, whilst the third patient showed an affection of the apex of the lung which aroused suspicions of tuberculosis. Tubercle bacilli had not been found, but this is no absolute proof of the non-existence of tuberculosis. Koch's fluid was injected on Sunday; no reaction ensued, which is a conclusive proof that the affection is not tuberculous. Professor Gerhardt, in conclusion, spoke some serious words of warning. He said it was absurd to imagine that Koch's treatment was of so simple a character that by subcutaneous injection consumption could be simply driven out of the body; on the contrary, in order to apply it successfully, the physician would have to use the most careful discrimination.

Professor Koch's Syringe.—We have received from the maker, Herr E. Kraus, 55 Kommandantenstrasse, Berlin, an electrotype of the syringe used by Professor Koch and his colleagues in their antituberculous inoculations. As will be seen, it is a slightly modified form of the ordinary Pravaz's hypodermic syringe.

The instrument consists (1) in an exactly-graduated glass cylinder of the capacity of two grammes, with a conical nozzle for the reception of the hollow needle;

(2) a stopcock of German silver with an elastic ball; (3) two hollow needles. When the stopcock is closed, the upper part of the glass cylinder filled with injection fluid



is fixed into the hermetically closed cone of the German-silver stopcock. After the canula is introduced, the stopcock is opened and the remedy injected by pressure on the India-rubber ball.—*British Medical Journal*, November 22, 1890.

Dr. Henry Morris desires us to state that he has not been and is not a candidate for the Chair of Therapeutics and Materia Medica at the Jefferson Medical College.

Mutter Lectures of the College of Physicians of Philadelphia.—The course of lectures on surgical pathology provide in accordance with the will of the late Professor Thomas D. Mütter, will be delivered during 1890–91, by Professor Roswell Park, of Buffalo, New York.

The first series of five lectures will be given in the Hall of the College of Physicians, corner of Thirteenth and Locust Streets, on December 4th, 5th, 6th, 8th, and 9th, at 8.15 P. M.

The subjects are as follows:

1. Introductory. Study of the blood and of some phases of the inflammatory process. Thrombosis, Embolism, Hæmoglobin, Oligochromæmia, and Ptomaïnes. Conditions predisposing to infection.

2. A study of pus and of pyogenic organisms, obligate and facultative.

3. Surgical sepsis and the organisms which produce it. *Résumé* of experimental work, Surgical Fever, Intestinal Toxæmia, Sapræmia, Septicæmia, and Pyæmia.

4. Peritonitis—forms and causes. Testing the relative values of antiseptics.

5. Tetany and Tetanus.

The medical profession are cordially invited to be present.

William Hunt,
Chairman of the Committee.

D. Hayes Agnew,
President

Prize of the New York State Medical Association.—Dr. J. G. Orton, ex-President of the New York State Medical Association, has offered a prize of $100 for the best short popular essay on some subject connected with practical sanitation, under the following conditions:

1. Competition to be open to all.

2. Essays to be forwarded to the Secretary of the Association, Dr. E. D. Ferguson, Troy, N. Y., not later than August 1, 1891, accompanied by the name of the author under separate seal.

3. Examination and award to be made by a committee appointed by the Council of the Association.

4. The successful essay to be read at the next annual meeting of the Association, and, if approved by the Council, to be offered for publication in the secular press, and issued in tract form or otherwise for general circulation.

5. Authors of essays, unsuccessful so far as the prize is concerned, but found worthy of special commendation, to receive intimation as to a proper disposition to be made of them.

The Congress of Hygiene and Demography.—The Congress of Hygiene and Demography will be held in London during the week beginning August 10, 1891.

The governments of all countries and municipalities, and all public health authorities, universities, colleges, and societies occupied in the study of the sciences more or less immediately connected with hygiene are invited to coöperate and appoint delegates to represent them at the Congress. The Prince of Wales will preside.

A committee of organization has been formed, of which Sir Douglas Galton is chairman, and Professor W. H. Corfield and Mr. Shirley F. Murphy are honorary secretaries. An exhibition of articles of hygienic interest will be held in connection with the Congress. The last of these congresses was held in Vienna in 1887, and was attended by more than 2000 persons, and it is expected that the London meeting will be one of great magnitude and importance.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING NOVEMBER 29, 1890.

Crawford, M. H., *Passed Assistant Surgeon.*—Ordered to the Receiving-ship "Independence."

Marsteller, E. H., *Passed Assistant Surgeon.*—Ordered to the U. S. S. "Petrel."

Nash, Francis S., *Passed Assistant Surgeon.*—Resigned from the U. S. Navy, to take effect November 23, 1891.

Cordeiro, F. J. B., *Passed Assistant Surgeon.*—Granted extension of leave for four months, with permission to leave the United States.

Lansdale, Philip, *Medical Director* (Retired).—Granted one year's leave, with permission to leave the United States.

Adrian, Richard Alfred.—Commissioned an Assistant Surgeon in the U. S. Navy, from November 24, 1890.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FROM NOVEMBER 15 TO NOVEMBER 22, 1890.

Fessenden, C. S. D., *Surgeon.*—Granted leave of absence for fourteen days, November 22, 1890.

Austin, H. W., *Surgeon.*—Detailed as Chairman of a Board of Medical Officers to convene, December 1, 1890, in Washington, D. C., November 19, 1890.

Irwin, Fairfax, *Surgeon.*—Detailed as a member of a Board of Medical Officers to convene, December 1, 1890, in Washington, D. C., November 19, 1890.

Kinyoun, J. J., *Assistant Surgeon.*—Detailed as Recorder of a Board of Medical Officers to convene, December 1, 1890, in Washington, D. C., November 19, 1890.

Woodward, R. M., *Assistant Surgeon.*—Granted leave of absence for fourteen days, November 21, 1890.

Condict, A. W., *Assistant Surgeon.*—To proceed to Cairo, Ill., for temporary duty, November 19, 1890.

Stimpson, W. G., *Assistant Surgeon.*—To proceed to Cape Charles Quarantine, for temporary duty, November 20, 1890.

Promotion.

Kinyoun, J. J., *Passed Assistant Surgeon.*—Commissioned as Passed Assistant Surgeon by the President, November 21, 1890.

Appointment.

Cofer, L. E., *Assistant Surgeon*—Commissioned as Assistant Surgeon by the President, November 21, 1890.

ORIGINAL LECTURES.

THE CURE OF PROCIDENTIA UTERI.

A Clinical Lecture
delivered at the Woman's Hospital of Chicago,
October 20, 1890.

BY HENRY T. BYFORD, M.D.,

PROFESSOR OF CLINICAL GYNECOLOGY IN THE WOMAN'S HOSPITAL; PROFESSOR OF GYNECOLOGY IN THE CHICAGO POST-GRADUATE MEDICAL SCHOOL; GYNECOLOGIST TO ST LUKE'S HOSPITAL; SURGEON TO THE WOMAN'S HOSPITAL OF CHICAGO.

LADIES AND GENTLEMEN: While our patient is being anæsthetized I will call your attention to the conditions upon which procidentia uteri depends. The first conditions to be taken into consideration are, of course, the natural position and attachments of the uterus. The normal viscus is small, weighs but four ounces, and is situated well up in the pelvis, with the os pointing backward toward the lower end of the sacrum. Its supports may be divided into three sets: the superior or sustaining, the inferior or retaining, and the external or supplementary.

The pelvic organs are roofed over by the peritoneal membrane, which is reflected about them like gables, and which, with the muscular and fibrous tissue in and under them, constitutes the sustaining supports or ligaments. The bladder, uterus, and rectum project upward through this roof of peritoneum like domes, towers, or chimneys, and, as you know, are held in place by a great abundance of connective tissue. Were it not for the variable abdominal pressure over them they would be adequately sustained by these attachments. But when the ordinary pressure is augmented by the muscular action of the individual, this elastic connective tissue is stretched, and the organs come down against the pelvic floor. Here they are retained until the cessation of this additional pressure allows them to be drawn back into place. The pelvic floor consists of the levator ani muscle and fascia, the coccyx, and the tissues of the interior pelvic walls.

The bladder, the uterus, and the rectum each constitutes a chamber in the structure, and each has its outlet, viz., the urethra, the vagina, and the anus. These outlets terminate at the pelvic portico or perineum proper, which, as Emmet has told us, acts as their support—but supports the uterus only in a supplementary manner. The perineum consists mainly of the triangular ligament, and the levator vaginæ, constrictor cunni, transversus perinei, and sphincter ani muscles, with their fasciæ. Now if the perineal body be torn, the urethra, vagina, and rectum having lost a part of their support, tend to protrude, and in protruding weaken the contiguous portions of the pelvic floor and connective tissue. Lacerate the pelvic floor also, and the uterus has nothing to prevent it from protruding under increased abdominal pressure except the elastic superior supports, which, in turn, are weakened by the laxity of contiguous tissues under them. Now let the uterus, particularly its cervical portion, become enlarged from chronic disease; or let it remain in a state of subinvolution, along with subinvolution of the other pelvic tissues; or let a chronic diarrhœa, or proctitis, or a general condition of debility, impair the integrity of the pelvic connective tissue, and procidentia will result.

Our patient, as most of you can see, is the one upon whom we performed a high amputation of the cervix two weeks ago. She acquired lacerations of the cervix and perineum in childbirth, followed by subinvolution of the uterus and vagina, and most of the time during the nine or ten years that have followed, she has suffered from diarrhœa. Two weeks ago the fundus lay on the relaxed perineal body, and the enlarged and lacerated cervix protruded about three inches from the vulva, bringing the vagina, bladder, and rectum down also. The uterus measured four inches in length. The pelvis would hold no pessary, and her condition was one of extreme misery.

As it would have been unscientific to attempt to keep a uterus and vagina of that size in this pelvis, I made an oval incision around the cervix and about half an inch away from it, so as to cut off some of the vaginal walls. I then dissected up the connective tissue as high as the uterine arteries, ligated these arteries with strong catgut, and continued the separation of the connective tissue as high as the internal os. Drawing the uterus well out, I put an elastic ligature about it and the protruding vagina, and proceeded to amputate the cervix near its junction with the corpus. I then drew the vaginal walls together over the stump and stitched the edges to each other and to the cervical mucous membrane. As is often the case, the internal os was very small, even though the uterus was enlarged, and the cervix had been lacerated and everted. I then tamponed the uterus in position for twenty-four hours, and have subsequently kept the woman in bed, using one-per-cent. carbolic acid douches after each urination. The uterus is about the normal size, and has been in a normal position ever since. I may say that the two weeks she has been in bed, and the four that she will remain in bed after to-day's operation, constitute quite an important part of the treatment. The vagina, as is apparent to you, has contracted in the upper part as a result of the first operation, and our endeavor to-day will be to contract its lower portions and the perineum. At the same time I will give it a new attachment to the tissues at the sides of the pelvis over the deeper portions of the levator ani muscles, by a procedure somewhat different from those that have been employed by other operators.

Having cleansed and disinfected the field of operation, I remove a strip of mucous membrane nearly one inch

wide from the left lateral vaginal wall just above the sulcus and extending from the caruncule about two inches back toward the cervix. The wound bleeds profusely, as I knew it would, but the bleeding does not matter, as I shall immediately close the wound with uninterrupted catgut sutures. The stitches are passed deeply into the fascia at the upper edge, then out into the wound, then into the bottom and through the lower edge, so as to gather up the looser tissue and lower edge, and bring them to the upper edge and firmer fascia. Having completely closed this wound, I put in two silkworm-gut sutures to relieve the strain upon the catgut. I now quickly excise a similar strip from the right vaginal wall, and close it in the same way. The posterior vaginal and anterior rectal walls are now drawn well up in their proper places and firmly held, while the vagina has become quite narrow, except under the neck of the bladder.

There is one point in connection with this operation on the lateral vaginal wall that deserves your attention, namely, it is not merely a denudation but a removal of the entire thickness of the mucous membrane, and opens into the cellular tissue. The vagina is thus not only narrowed, but the connective-tissue attachments are in part restored. This is an idea that has been overlooked in the various operations for prolapse. But the frequent failure of methods which are designed merely to narrow the vagina and build a perineal body afford convincing proof of its importance.

With this long-handled needle I now pass a silk suture around a circular space of sagging vaginal wall, about the size of a silver half-dollar, just under the neck of the bladder, cut out the mucous membrane within the circle, and draw the edges together with the silk puckering string, as if it were the mouth of a purse. Now all is tight internally, and we have but to reconstruct a perineal body externally.

For our present purpose nothing is better than Tait's flap-operation. Entering the point of the scissors high on the inside of the left labium, and a short distance external to the vaginal sutures, I cut deep into the tissues, and carry the point of the scissors down the labium, across the perineal body, a little above the sphincter ani, and upward on the other labium. With a few additional snips I lay open the tissue quite deeply, catch up the centre of the superior edge of the wound with forceps, and draw it well up so as to make the wound more perpendicular than transverse. You will observe that this wound has no connection with the lateral vaginal wounds previously sutured, being entirely below them. Commencing at the upper end of the labial incision, I pass silkworm-gut sutures into the raw tissues under, but not including, the edge of the skin, and bring them out on the other side, also under the edge. Now that they all are in, I find it more convenient to tie from below upward, and the patient is ready to be cleansed and put to bed. Plain vaginal douches will be given after each urination for forty eight hours, then douches of one-per-cent. carbolic acid solution. In four weeks she will be permitted to get up and go home.

It is well for me to remind you that this procedure will not do for every case. Had the uterus remained retroverted after the amputation of the cervix, I should have performed Alexander's operation. The reason that the latter operation cannot always be depended upon is because the round ligaments are often stretched to such an extent that they cannot be found or utilized. The popular objection that the ligaments are not strong enough to hold up the uterus is based upon ignorance of their action. They merely hold the fundus forward so that abdominal pressure will be exerted upon the posterior surface of the uterus, the retention of which, after it is placed in this advantageous position, is the work of other supports.

When the inguinal canals are opened during the Alexander operation, it becomes an easy matter to suspend the prolapsed bladder. We may cut through the posterior walls of the canals, separate the loose connective tissue from the pubic bones, pass sutures down through the vaginal walls on either side of the neck of the bladder, draw up the prolapsed vesico-vaginal septum, and stitch it behind the pubes. I prefer to use silkworm-gut sutures, and include a portion of the vaginal walls and pillars of the external inguinal ring in each.

Shortening the sacro-uterine ligaments has been done in various ways, both through the vagina and in the abdominal cavity. Cauterization of the vagina, incomplete closure by uniting the denuded anterior and posterior walls, or the denuded lateral walls; removal of almost the entire anterior or posterior wall, etc., have been tried with varying success. Our time is too valuable to allow us to describe the numerous forms of denudations in use, such as triangles, quadrilaterals, pentagons, circles, ovals, parallelograms, monograms, butterflies, and other figures of professorial fancy.

In order to extricate our minds from this confusion of methods, we should never forget that in each case there are certain defects either of the superior, inferior, or supplementary supports which must be remedied. The perineal body, pelvic floor, connective-tissue attachments, uterine ligaments, or the vagina and uterus themselves, must be thought of, while the Chinese puzzle of denudation, as figured in many of the text-books, should be duly treasured as an interesting relic of mediæval art.

In some slight cases Thure Brandt's uterine massage, by restoring tone to the muscular fibres, suffices for a cure.

In case of diseased ovaries, we may be justified in opening the abdominal cavity, removing them with as much of the relaxed broad ligaments as possible, and stitching the stumps to the anterior abdominal walls. An operation upon the sacro-uterine folds would also be justifiable at such a time.

Removing the entire uterus *per vaginam* will, of course, cure the procidentia uteri. But if we confine ourselves to that, the relaxed tissues will be apt to permit the vagina and intestines to protrude, and thus fail to cure the patient. I have, in fact, had to perform some of these operations after the uterus had been taken out. If, however, we decide to remove the uterus for procidentia, we should at the same time remove all the redundant vaginal wall in such a manner as to secure lateral connective-tissue attachments.

The Buffalo Medical College.—It is said that the buildings of the Buffalo Medical College will soon be remodelled and enlarged.

ORIGINAL ARTICLES.

THE USELESSNESS OF SPLINTS IN FRACTURE OF THE LOWER END OF THE RADIUS.[1]

BY JOHN B. ROBERTS, M.D.,
PROFESSOR OF SURGERY IN THE PHILADELPHIA POLYCLINIC AND IN THE WOMAN'S MEDICAL COLLEGE OF PENNSYLVANIA.

THE treatment of fracture of the lower end of the radius is exceedingly satisfactory, because the character of the injury seldom varies and because the results obtained are usually good both in rapidity of cure and in perfect restoration of function.

This statement is, perhaps, unexpected, since it is not unusual to find the opinion expressed in text-books that this fracture is troublesome to treat, and very liable to be followed by deformity of the wrist and stiffness of the fingers. I am convinced that such unfortunate results usually come from mismanagement of the fracture, and are due to a want of appreciation of the nature of the lesion, and of the necessity for forcible reduction immediately after its receipt. These errors of judgment and treatment are perpetuated by the current belief that the essential treatment of a fracture is the application of a splint.

I propose to show that in the great majority of cases fracture of the lower end of the radius needs no splint; and hence that splints for this injury are usually useless. If the tendency to use a splint impels the practitioner to neglect the all-important reduction of the fracture, my position, it seems to me, is strengthened.

The innumerable forms of splint devised for fracture of the lower end of the radius show how much this very common injury has interested the profession. Some of these splints have done great harm because they have misled the practitioner as to the nature of the lesion. A few of them are very good, in that they have been devised in accordance with the anatomy and pathology of the osseous lesion. As, however, in the vast majority of cases, none of them is really needed they are practically useless. The fact that positive harm is liable to be done by their use is a point in advocacy of the abandonment of all such appliances.

The usual cause of the injury is forced extension of the radio-carpal joint, which produces a transverse disruption through the lower end of the radius from three-eighths to one-half an inch above the articular surface. The characteristic deformity is caused by the fracturing force driving the lower fragment upward and backward upon the shaft, or thrusting the shaft downward and under that fragment; so that it is caught or impacted upon the dorsal edge of the shaft-fragment. Occasionally there is a tendency to lateral or antero-posterior obliquity of the line of fracture, but this is rather uncommon. The displacement sometimes occurs much more markedly at the radial than at the ulnar side of the lower fragment, which is then tilted obliquely backward, carrying the styloid process of the radius upward and backward, so that it is on a level with, or even higher than, the styloid process of the ulna. This angular displacement tends to throw the articular surface with the attached carpus upward and backward to the radial side, causing thereby undue prominence of the lower end of the ulna.

Muscular action has nothing to do with the production or continuance of the deformity. In cases in which the fracturing force has not been sufficient to cause displacement, no deformity exists, and in such instances the diagnosis rests upon a localized point of great tenderness about half an inch above the wrist-joint.

Sometimes comminution of the lower fragment takes place so that lines of fracture enter the radio-carpal joint. The ligaments and cartilages are sometimes extensively injured, and sometimes there occurs actual loss of substance by crushing and pulverizing of the bone tissue. These complications, except that of comminution, are quite rare.

Reduction of the fracture, the most important element in the treatment of the injury, is often ineffectually accomplished, or, indeed, not attempted. This is owing to ignorance rather than carelessness on the part of the attendant. When reduction is once thoroughly accomplished, displacement is not apt to recur, because the broad rough surfaces of bone are held together by their serrations, and because there are no muscular masses tending to displace the fragments.

The condition, it will be observed, is quite different from oblique fracture of the shaft of a bone, in which it is often difficult to maintain accurate apposition because of the muscular displacing forces. Hence if reduction, which is the essential in treatment, is properly performed, no splint is needed. On the other hand, if reduction is neglected, no splint will act as a substitute for it. If reduction has been properly accomplished, an improper splint may displace the lower fragment and cause recurrence of the deformity. Hence, abandonment of splints is usually the proper course to pursue, and probably the most judicious method of treatment to advocate and teach.

Comminuted fractures, of course, need more support than do non-comminuted ones; but even here, the simple support of a bandage applied in a circular manner, or of strips of adhesive plaster wound around the wrist like a collar will usually be found sufficient.

[1] Read before the Philadelphia Academy of Surgery, November 3, 1890.

In uncomplicated fractures treatment is required for about three weeks.

Perfect function of the wrist and fingers may be expected in nearly all cases; provided that reduction has been properly effected immediately after the injury, and provided that the fingers have not been restricted in motion at any time during the treatment. Slight stiffness of the wrist may be expected for a few weeks in complicated cases; and in such injuries some thickening about the seat of the fracture will persist for two or three months. Slight shortening of the radius, due to loss of tissue by crushing and absorption, occurs in most cases, but the resulting inclination of the hand to the radial side in well-treated cases of average severity can usually be detected only by very close scrutiny.

The statement of some authors that long-continued disability of the wrist and fingers is to be expected is absolutely untrue in the average case of fracture of the lower end of the radius; and is due to observation of cases improperly treated.

The danger of many of the splints advocated for this fracture is due to the non-recognition by their respective inventors of the curved or arched shape of the palmar surface of the lower third of the radius. The dorsum of the bone when covered with the tendons is straight, but the palmar surface is curved. It is readily understood, therefore, that the application of any straight splint (such as that called Bond's splint) to the palmar surface of the broken radius has a tendency to displace the lower fragment upward again, as soon as the bandage which retains the splint in position is applied. A straight splint may, however, be applied with propriety to the back of the wrist. I have used with satisfaction two or three pieces of whalebone held in position by a strip of adhesive plaster. Any rigid article, such as a piece of steel or wood, half an inch wide and five or six inches long, will answer the purpose. The truth is, however, that in a person of ordinary intelligence, who will avoid subjecting the bone to severe strains, there is no need of any splint or rigid support. Exceptions to this rule may perhaps be found in the case of refractory children and of ignorant or stubborn adults. The fact that these persons are liable to use the hand at an early period, and in such a way as to cause a *slight* risk of displacement of the fragments, is evidence of the simplicity and painlessness of the injury and of the satisfactory manner in which union takes place, if reduction has been properly effected.

That the treatment of this fracture is misunderstood by many practitioners is evident to me from the fact that I have repeatedly been obliged to refracture and reduce partially-united fractures of this kind after several weeks' treatment in splints. In a number of instances an exceedingly good splint had been applied though the fracture had not been reduced. A quite recent experience of this kind in which I refractured the bone eight weeks after the injury has forcibly brought the subject to my mind.

Osteotomy, for the purpose of correcting such deformities, is seldom if ever required. I have known a deformed fracture of the radius to be broken for re-adjustment five and a half months after the injury. To do this requires considerable power, but it can generally be accomplished by forcibly bending the bone across the operator's knee.

A few years ago, while holding a position as out-patient surgeon in one of the hospitals of this city, I had occasion to treat, within less than three months, forty-two cases of fracture of the lower end of the radius. Some of these were treated with the moulded metal splint recommended by Dr. Levis; others were dressed with a straight dorsal splint of wood; while in some the wrist was immobilized by means of a single strip of steel, or two or three strips of whalebone applied to the dorsum of the joint by means of adhesive plaster encircling the limb. A few were treated during a part of the time by applying to the palmar surface a curved steel strip, such as the "busk-bones" of corsets.

The accompanying table gives a brief account of the treatment, the time the splints were worn, and the results in these cases. In a few instances no results were recorded in the case-book, either because the patient discontinued attendance or because no unusual condition was found. It is very probable that in the latter case there was not much deformity or disability, else it would have been mentioned. There are a few other cases in the table in which the record is deficient in detail, because the patients were still under treatment when my term of service was completed.

It will be observed that six cases came to me with the lower fragment still unreduced, although in each instance a splint had been applied. In five of these cases Levis's moulded splint, the best splint manufactured for this fracture, had been applied. This fact proves my assertion that it is the custom of many to apply a splint, and often a very proper one, without reducing the fracture. It is this belief in the therapeutic value of the splint which causes many physicians to have bad results in the treatment of this fracture. If the profession were made to understand that no splint can be constructed which will take the place of reduction, better results would be more frequent.

It is interesting to note that all, or nearly all, of the cases tabulated had been originally dressed by the resident physicians belonging to the wards of the hospital. It is also worthy of comment that these residents belonged to a hospital with which at the time were connected two surgeons who have

TABLE OF FRACTURES OF THE LOWER END OF RADIUS.

Age	Sex.	Treatment.	Days splint worn.	Result.	Remarks.
70	F.	Metal splint	...		Diagnosed sprain at hospital.
21	M.	Metal splint	8		
50	M.	Metal splint	17		
16	M.	Metal splint	9	Good union; no stiffness of fingers of wrist.	
63	M.	Metal splint.			
12	M.	Metal splint	17	No deformity; good motion; no stiffness.	
12	M.	Dorsal straight splint	17		Palmar surface was vesicated by inflammation; hence, used dorsal splint.
60	F.	Metal splint	20	Good motion.	
24	M.	Metal splint	10	Good motion; no deformity.	
65	M.	Metal splint	9	No deformity; good motion.	
38	F.	Metal splint; twelve days later steel strip on dorsum.	18		
40	F.	Metal splint	5	No deformity; no stiffness.	Examined five and a half weeks later; slight stiffness of wrist; some shortening on radial side.
19	M.	Dorsal straight splint put on November 3d, when I first saw him; had Bond's splint on previously.	13	No stiffness; some shortening on radial side.	Weak flexion of fingers; had palmar wound, but not down to fracture.
15	M.	Metal splint	14	Good motion; some bowing at lower end.	
16	M.	Metal splint; three days later, steel strip on dorsum.	7	Motion perfect.	Fracture three days old when first treated, and no deformity then existed.
55	F.	Metal splint	20	Some deformity; slight stiffness of forefinger.	Kept at home by illness; not seen regularly.
13	M.	Metal splint; one day later, steel strip on dorsum.			
68	M.	Metal splint	25 ?	Considerable stiffness.	
48	F.	Metal splint	...		When fracture was two days old reduced again; much comminution: no record to show that it was properly reduced before I saw her.
18	M.	Metal splint; two days later, steel strip on dorsum.	10	Deformity from callus; good motion.	Great deformity before reduction.
44	F.	Metal splint, two days ago, outside; but not reduced. Reduced, applied curved corset steel to palmar surface.	10		The time given is from the time I reduced the fracture.
17	M.	Metal splint; six days later whalebone strips to dorsum.	13	No deformity; perfect motion.	Great deformity before reduction under ether.
35	M.	Metal splint	14	No deformity; perfect motion.	
70	F.	Metal splint; two days later, curved corset steel to palmar surface.	15	No deformity; perfect motion.	
14	M.	Curved corset bone to palmar surface on day after injury; metal splint for one day.	8		
25	F.	Metal splint, three days ago, outside, but not reduced. Reduction, metal splint for one day, then curved corset steel to palmar surface.	7		The time given is from the time I reduced the fracture.
15	F.	Metal splint	17	As no note was made, probably good result.	Treated in hospital; on admission great deformity, and had scalp wound; came to out-patient department after union had occurred.
26	M.	Metal splint, three days ago, outside; narrow curved corset steel to palmar surface	10	No deformity; no stiffness.	
39	F.	Metal splint.			
45	F.	Metal splint; three days later, curved corset steel to palmar surface.	13	Good result.	
35	F.	Metal splint			
54	F.	Metal splint; four days later, steel strip on dorsal surface.	...	No deformity.	
55	M.	Metal splint	...	Good result.	
35	F.	Metal splint; eleven days later, steel strip on dorsal surface.	...		Not seen after first dressing until eleven days had elapsed; sick in bed at home during that time.
48	F.	Metal splint, two days ago, outside, but not reduced. Reduction.			
29	F.	Metal splint, two days ago, outside, but not reduced. Reduction.			
25	M.	Narrow corset steel on palmar surface, as there was no deformity.			
30	M.	Metal splint.			
52	F.	Metal splint.			
50	F.	Metal splint.			
40	F.	Bond's splint outside, but not reduced. Reduction, metal splint.			
48	M.	Metal splint	15	No deformity; perfect motion.	Much pain during treatment; chloral and morphine given; said to have been broken two years before.

written and done most effective work in teaching the pathology and proper treatment of this particular injury.

The table is instructive, I think, as showing that perfect motion without special deformity was obtained in almost every case. It must be remembered, in addition, that these records were made a few weeks after the receipt of the injury, and that the results, so good at that time, probably became more perfect after the lapse of a longer period.

At the present time I should be inclined in nearly all cases to treat the fracture without using any splint at all; or, at most, I should employ only a thin strip of steel or zinc, or a couple of pieces of whalebone, six inches long, applied to the dorsum of the wrist, and held in place by strips of adhesive plaster.

When the tabulated cases were treated the time during which restrictive dressings were continued was probably less than would be advocated by most surgeons. I have seen no reason to alter my practice in this regard, except perhaps to shorten the time still more. I am now convinced that a roller bandage or a strip of adhesive plaster applied to the wrist in a circular manner is all that is necessary, except in unusually complicated fractures. All ordinary forms of splints should, as a rule, be discarded as useless or dangerous.

The proper treatment of fracture of the lower end of the radius is *reduction*. Little else is required in the ordinary cases.

DISCUSSION.

In discussing this paper DR. WILLIAM HUNT said that he fully agreed with Dr. Roberts that the proper treatment of these fractures is prompt reduction, and that it makes very little difference what splint, if any, is used afterward, provided the pathology and the anatomy are kept in mind. He, however, advocated the use of a splint of some kind in nearly all cases, if only to relieve the patient of pain through the sense of support. He also said that the majority of Dr. Roberts's cases were last seen two or three weeks after they were discharged, whereas, it is six months or a year after the accident that the deformity usually becomes most manifest, as a result of the subsidence of the œdema. We may think that the result is perfect, but when the swelling passes away we may find that there is distinct deformity.

Years ago he had an opportunity to study the pathology of this fracture in a case in which it was necessary to amputate the arm on account of an injury of the elbow-joint. There was at the same time a characteristic radial fracture. In his account of the condition found he stated that there was no displacement of the ulnar side in ordinary cases, but that the hand, losing the support of the radius, falls away, leaving the ulna projecting. This is the deformity which in most cases becomes more apparent five or six months after the injury, and in the majority it is unavoidable. It does not, however, interfere with the use of the hand. Although the treatment of fractures of the lower end of the radius is reduction, we should nearly always put the part at rest with a splint of some kind.

DR. O. H. ALLIS regretted that Dr. Roberts was not present to take part in the discussion. One of the saddest experiences in the duties of a physician is learning that he is not at liberty to do that which in his judgment is best; and this is especially true in the treatment of fractures. There is no department of medical or surgical practice so likely to drag the surgeon into the courts as that of fracture. There are defects other than deformity over which a surgeon has no control, and if a surgeon were to treat a fracture of any kind without splints, and deformity, paralysis, or any permanent disability ensued, the patient would have a strong case in the courts; and very few of the defendant's medical witnesses would be able to sustain him in his course.

THE PRESIDENT, DR. AGNEW, said that probably all would agree with Dr. Roberts that these fractures are badly reduced, and that if properly adjusted it matters little what splint is employed to maintain the fragments in position. To allow the patient, however, to go without any means for protecting the parts, is dangerous, and calculated to expose the surgeon to a suit for damages in the event of an accident, especially with a careless patient, who might take unwarranted liberties with the arm. It must not be overlooked that there are several tendons attached by loops of fascia to the bone, and one tendon implanted upon the latter, though Dr. Roberts states that there are no muscles to cause displacement. It will be difficult to persuade the profession, many of whom have had years of experience in the management of these fractures, to leave the bone without some fixed support.

DR. ALLIS said that with Dr. Roberts he recently attended a clinic of Dr. Pilcher's, in New York. A case was exhibited which had been treated without a splint. This was the first case he had seen treated in this manner, and he thought that it required a good deal of courage on the part of the surgeon. The necessity for a splint is less if the surgeon can see his cases frequently, than as in the country, where the cases cannot be seen so regularly.

DR. L. W. STEINBACH believed that he had seen almost all the cases to which Dr. Roberts referred, and that splints, in the proper sense of that term, were not used, although a strip of adhesive plaster was sometimes applied to remind the patient of the injury. Dr. Roberts sometimes used a corset steel with the curved end applied to the inferior part of the forearm and the hand.

He thought that Dr. Roberts made an important point when he said that the physician's mind should be disabused of the idea of the necessity of a splint. The physician often thinks that when he has applied a splint he has done his entire duty, and rarely dwells upon the importance of reduction. In many of the cases reported in the table a splint had been applied before the fracture was reduced.

DR. DEFOREST WILLARD, while recognizing that the splint does not cure the fracture and that reduction is the important element in the treatment, yet could see no reason why in the majority of cases of careless boys and men, and in fact in nearly all cases, we should not endeavor to maintain the fracture in position after reduc-

tion. Both the injury and muscular action aid in displacing the fragments. Splints are of use in maintaining the reduction, and are safer than leaving the individual simply with a piece of adhesive plaster, which, while it is a reminder, yet will not prevent injury from blows.

DR. JOHN B. DEAVER agreed with Dr. Roberts in some particulars, but said that if he did not know Dr. Roberts so well he would question the diagnosis in some of the cases of fracture of the lower end of the radius treated without splints. In the majority of his own cases the line of fracture was oblique and involved more than one-fourth of an inch of the radius — sometimes as much as one inch or one inch and a half. The extensor muscles of the thumb and the extensors of the carpus aid in producing deformity. He believed that in some of these cases the muscular fibres become entangled between the fragments. Under such circumstances it would be almost, if not entirely, impossible to keep the parts in position without support. One of the cardinal principles in the treatment of fracture is immobilization of the joints on the proximal and distal sides of the fracture. This is just as true in fractures of the lower end of the radius, as it is in fractures of both bones of the forearm. He would not permit a fracture of his own radius to be treated without a splint, and he would not treat a patient in that way. It is contrary to all anatomical and pathological teaching. A simple transverse fracture—which is rare—in an intelligent person, requires only a light splint.

In the correction of deformities due to badly-set fractures he believes that osteotomy is more scientific than re-fracture and causes less injury to the soft tissues.

DR. J. EWING MEARS said that the subject was an interesting one. It reminded him that years ago he in connection with the other resident physicians of a large hospital came to the conclusion that the binder after labor was of no service and that it had simply a moral effect. During their term of service they tied a string around the abdomen after labor and believed that the effects were the same as those of a binder. He does not now believe that anything was gained by this, and thinks that patients would complain if obstetricians failed to apply a binder.

In regard to fractures of the lower end of the radius two points were dwelt upon. First, that there is no fracture in the body which is so often treated badly as this. It seems natural for the physician to suppose from the peculiar character of the splint usually employed that its simple application effects the reduction. Secondly, a properly-reduced fracture may result in deformity by reason of a badly-adapted splint. The treatment of fracture is reduction, and retention of the fragments by means of some appliance. The views expressed by others cover the entire ground. Dr. Hunt referred to an important point, namely, the comfort to the patient derived from a properly-applied support. And the President sounded a note of warning with regard to suits for malpractice in cases in which deformity may result.

DR. HUNT said that every hospital surgeon of large experience studies individual cases, and he could recall no ordinary fracture that he has not in some instances treated without splints. In these cases the fracture is reduced, placed in proper position and closely watched.

DR. ALLIS referred to the case of a man injured by a fall from a great height, who was brought to the Presbyterian Hospital, and died in about twenty hours. Among the injuries was a fracture of the lower end of the radius, which he dissected. The injury to the soft parts and bone was so great that if the man had lived the resulting inflammation would have unified all the tendons of the wrist so that no finger could move independently of the others. There was a fracture about three-fourths of an inch above the end of the bone, which ran part of the way across, then downward. The bone was broken into small pieces, as though the fragments had been forcibly rubbed together. The fragments were not interdigitating, and if placed in position would not have remained so. On the dorsal aspect, far removed from the seat of fracture, blood was found in the sheaths of the tendons and also in the bellies of the muscles. In cases of fracture we never know how much injury has been done at the time of the fracture. He has treated a woman who had a severe injury to the wrist from falling down stairs. It was compound, but at once made simple by organized blood-clot. The injury occurred three or four years ago, but the woman is still unable to close her hand. In other cases apparently with the same injury, the result is a perfect cure. The explanation of these cases is found in the different extent of the injury at the time of the accident.

THE MEDICAL TREATMENT OF PERITONITIS.[1]

BY JOSEPH EICHBERG, M.D.,
OF CINCINNATI, OHIO.

THE treatment of peritonitis must necessarily be adapted to the cause, and varies greatly as we are dealing with a primary or a secondary form of the affection. Yet, in many cases, the search for the cause is neither easy nor successful; and while uncertainty on this point may exist, our duty to the patient demands prompt action. The whole history of this affection is so recent that it is rather to be marvelled at that the plan of treatment now generally adopted has been matured in so short a time, and that, if properly carried out, it will in many cases prove so successful, independent of the causal condition.

A moment's consideration of the natural function of the peritoneum will help us considerably to understand why certain measures must be used to attain a favorable issue. As a delicate, smooth investment of nearly all the important organs of the abdominal cavity, its presence greatly facilitates those constant changes of size, position, and mutual relation that result from the various phases of the digestive process; its surface, kept constantly moist by the lymph that finds its way into the cavity, is never with an excess of fluid, because of stomata, or little lymph-mouths, that readily afford exit into the lymphatic circulation of any fluid that may

[1] Read before the Southwestern Ohio Medical Association, October 7, 1890.

accumulate in undue proportions—under physiological conditions.

With the appearance of inflammation the smooth, pliant, moist covering of the abdominal viscera becomes turgid and roughened, its surface covered with a viscid rather than a liquid product, its stomata closed, its cavity filled with the accumulated inflammatory exudations, for which there is no escape. It is now that the necessity for treatment arises. The patient, in the great majority of cases, experiences that symptom, common to many affections, of pain, and pain in a most severe and intolerable form. It is here that we have an indication both causal and symptomatic, for pain itself is prostrating, and pain will kill. The organs covered by the peritoneum are richly supplied with nervous connections, and through these they influence by reflex action the heart and circulation. We know the sudden, it may be fatal, collapse that follows a severe blow or injury upon the abdomen, and it is not difficult to believe that an irritation of less intensity and longer duration would bring about similar results. The pain in peritonitis is continuous, exaggerated by every movement, by every breath; it excludes every other consideration, and prevents sleep and needed rest. It is here that opium comes to our aid—the sheet-anchor, as it has been called, in peritonitis, the splint to the wounded peritoneum. I speak now of cases of acute diffuse peritonitis, the cases that are commonly met with.

It has seemed singular to me, after all that has been written and spoken upon this subject, that it should so frequently be necessary to encourage physicians to a more ready resort to this agent. It would seem that the proper amount of attention has not been given to the teachings of Alonzo Clark, who has summed up his own therapeutic experience of more than fifty years in the article upon this subject in Pepper's *System of Medicine*. Why it is that where such obvious indications for a remedy exist, so many medical men manifest an ill-founded timidity I cannot understand. Assuredly, it can not be the fault of their teaching; and if they only dared to use it properly, their first experience with opium in peritonitis would soon give them the needed confidence to do right by their patients. I feel very strongly upon this point, because it has happened to me to see several cases that made a lasting and very unfavorable impression. In one of these, a case of puerperal peritonitis, seen in consultation not long ago, the patient had been receiving for six days—mark it well—an average of one-fourth of a grain of morphine daily. She had not slept one hour in all that time, and, it is almost needless to say, she died. In another case of acute peritonitis in a boy of fourteen years, I was assured by the attending physician that he gave a hypodermic injection of an eighth of a grain of morphine as often as he thought necessary—as though it were not necessary every half-hour!

The average medical graduate leaves college with the carefully-acquired information that the dose of opium is from one-fourth to one-half a grain, every three or four hours, but that there are marked idiosyncrasies, and that its administration must be anxiously watched. He will, accordingly, treat his case of peritonitis on this plan, constantly feeling uneasy lest in his absence the patient develop narcotism. Finding that no symptoms of poisoning develop he will rest satisfied that he has done the full measure of his duty, and will repeat the small dose every three or four hours in his next case.

It is no imaginary picture that I am drawing; it is what I myself have seen; and it is time that the profession learned to regard this timorous, faint-hearted misuse of opium, deceiving alike to the practitioner and the patient, as malpractice; as criminal as the neglect to recognize a fracture, and place it in a suitable dressing. It has been said that there is no dose of opium for pain. This may be extended, and it may be as truthfully said that the smallest suitable dose of opium in peritonitis is that which will promptly carry the patient to the limits of narcotism, and that the frequency for its repetition is to be determined solely by the degree of narcotism. It is not conscientious regard for the patient's life that prevents the physician from following this plan. It is his own lack of courage which sacrifices the patient.

I am fully aware of arguments that have been advanced in answer to Dr. Clark's report of the case, who, at the height of the attack, received for six days the equivalent of from 421 to 467 grains of opium every twenty-four hours. It is said that of all this large amount but the smallest fraction was absorbed; that to get the proper dose it should be given hypodermically, etc. Supposing it was necessary to give 467 grains to obtain absorption for the amount required to cure the patient, then 467 grains was the proper dose in that case. Hypodermic medication, is unnecessary, as morphine can easily be given in concentrated solution by the mouth, and most of it will be absorbed before it enters the stomach, to say nothing of the intestines. The basis of some of the opposition is, that in the inflamed condition of the peritoneum, the mesentery and its contained vessels, and the intestines and their lacteals, are unable to perform their physiological duty. The full measure of their physiological duty, we will admit, but certainly not a large fraction of it, else how could nutrition be maintained?

A word more as to the opium treatment. To secure its best effect it must be given early. It has

for some time been my rule in every case commencing with fever, prostration, and an acute, localized, continuous pain, to begin the treatment at once with opium or morphine, without regard to the possibility of existing constipation. Should the painful symptoms subside in the course of a day or two the bowels may be opened by a mild saline cathartic, or, by what seems preferable to me, repeated minute doses of calomel; but opium first, and all the time, until convinced that peritonitis, in its diffuse form, has not developed. Little attention need be paid to the bowels at the start. Clark says that he has allowed patients to go for fourteen days without a stool.

The use of opium does not always prevent the regular evacuations, and I have seen a patient who had one movement daily during the entire course of the disease, though for two weeks he was receiving half a grain of morphine every hour, and, doubtless, many similar instances could be narrated. These cases should be regarded as exceptional, since the effect of the opium, as usually observed, is to retard greatly, if it does not wholly arrest, intestinal movements. By diminishing the frequency of respiration the opium tends to eliminate another source of pain, as well as to prevent that rapid spread of the disease which the constant attrition of diseased against healthy portions of the peritoneum will almost surely entail. Upon the circulation, too, the action of the opium must be regarded as largely beneficial. The slowing of the heart-beats with the rise in arterial tension following its use, are ample testimony that, if properly controlled, it is a cardiac tonic. We obtain this result at once, but it is necessary to carry the patient beyond this point, and to induce a sedative action on the circulation.

How are we to judge of the proper degree of narcotism, seeing that it is easy to carry the patient beyond the desired point, especially while employing such large doses? Not by the relief of pain, for this result may be attained early; nor by the contracted pupil, which also shows itself after very moderate doses. The index of the proper degree of narcotism is furnished by the respiration, the pulse, the continual drowsiness of the patient, and the partial relaxation of the abdominal wall. The frequency of the respirations, increased by the embarrassment of the abdominal movements, should be brought down to twelve or ten per minute, and maintained at this rate as long as the symptoms persist; should it fall below this limit, the interval between two successive doses can be lengthened. The pulse of peritonitis is hard and wiry; under the influence of these full doses of opium it becomes slow, soft, and compressible. The drowsiness of the patient is a symptom that should be watched by the physician himself, and not trusted to either nurse or attendant. It should be a drowsiness from which the patient can be readily roused, and should never be allowed to become a stupor. It is well in connection with this, to bear in mind that the maximum effect of any dose of opium or its derivatives is not obtained until three hours after administration—a safe criterion in deciding the frequency of repetition of our doses. With the patient fairly narcotized, there is slight relaxation of the abdominal muscles, the tympanites become less, with corresponding relief from the feeling of tension.

One effect incidental to the use of opium remains to be mentioned, and that is, its influence upon the secretions. It diminishes the saliva and the urine promptly and decidedly; it slightly increases the amount of the perspiration, and thus may aid in counteracting an excessive elevation of temperature. With regard to its use in peritonitis Brunton says that "Opium, by its action on the vaso-motor centre, and by its action also on the peripheral terminations of vaso-motor nerves, will prevent or diminish the reflex dilatation of the vessels, which the local irritation would otherwise produce; congestion will thus be diminished, and inflammation will be relieved." The action of opium in peritonitis is, therefore, probably twofold: First, it lessens peristaltic movements of the intestines, and thus diminishes local irritation; secondly, it lessens reflex activity of the centres through which local irritation causes dilatation of the vessels, and thus it diminishes peritoneal congestion.

The unpleasant effect of opium and its derivatives upon the secretions has led me to combine with it minute doses of a drug at one time very generally used in the management of this disease, but latterly decried on all sides: I refer to a salt of mercury, the mild chloride being the form commonly employed. The physiological effects of mercury and its salts upon the saliva and the urine are directly antagonistic to that of opium, both of these secretions being increased by its use. By combining with our opiate a small quantity of calomel we are frequently enabled to avoid the furred tongue, the dry lips, the pasty and unpleasant taste in the mouth, that so frequently attend the employment of large doses of opium. Nor need there be much fear of ptyalism when the two drugs are combined, as each in a measure counteracts the effects of the other. It is certain that mercury is tolerated better and for a longer time when combined with opium than when given alone.

Upon the urinary secretion the action of the mercurous salt is no less welcome. With the diminution of the secretion and the blunting of sensibility in the bladder, and with the impairment of muscular strength in the wall of this organ from the existing inflammation of its outer tunic, the expulsion of the

urine is often effected with the greatest difficulty; at times, indeed, it becomes impossible. It is in relieving these symptoms that calomel often assists, especially when combined with digitalis in small doses.

It seems to me that calomel has yet another virtue that entitles it to particular consideration here, namely, its action upon the intestine and intestinal contents. It cannot longer be gainsaid that mercury and its salts in physiological doses act as cholagogues. As Brunton says in his admirable work upon pharmacology, "The real action of mercury as a cholagogue consists, not in its stimulating the liver to form more bile, but in removing more readily from the body the bile which is already present in excess." It appears to perform this function by stimulating the upper part of the small intestine, and thus causing the evacuation of the bile before time has been allowed for its reabsorption. The reasons for this supposition are: (1) That mercury is so beneficial in bilious disorders; (2) that it does cause the appearance of bile in the stools, for Buchheim has proved by analysis that the green stools which occur after purgation by calomel owe their color to bile; and (3) that in the stools passed after mercurial purgatives, leucin and tyrosin, the products of pancreatic digestion, have been found.

Now we know that one office of the bile is to promote peristalsis. If we can assist in regularly transmitting to the lower part of the intestine some of this fluid we counteract by just so much the obstinate constipation that, if too long continued, may in itself constitute a menace to the patient suffering from acute peritonitis. Bile also has a tendency to prevent decomposition of the residual alimentary mass, and it is assisted in this by the presence of mercury, which acts as a disinfectant of the intestinal contents. In peritonitis this tendency to decomposition is greatly assisted by the sluggish movement or inaction of the bowel, by the temporarily increased local temperature, and by the presence of a large amount of inflammatory fluid, and any remedy which can counteract this tendency is useful.

It has been my practice to combine one-tenth of a grain of calomel with each half-grain of morphine, and to continue the administration of both drugs until the bowels are easily moved. This result is generally obtained on the fourth or fifth day, when several stools are apt to follow in quick succession. Should the tendency to diarrhœa become annoying, the calomel is discontinued and the patient given a little of Hope's camphor mixture.

The only contraindication for the use of opium may be furnished by the condition of the kidneys. Chronic interstitial nephritis, so insidious in its onset that the patient himself has never received any warning of its presence, is very apt to be revealed by the excessive effect of a single moderate dose of an opiate. The tendency to uræmia seems to be favored, if manifested before, or even to be developed, when not previously indicated, by the use of opium. Even in peritonitis, where there usually exists so remarkable a tolerance for this drug, the ill effects have not been wanting; so that patients suffering from peritonitis, occurring in the course of chronic Bright's disease, have quickly passed into a state of uræmic coma, with no symptoms of narcotism, and have died comatose, without rallying from the first attack.

My preference for morphine has always been strong, and I am in the habit of giving it in the form of a standard solution in cherry-laurel water, one grain to the drachm. Of this solution a sixth, fourth, third, or half can easily be given, and the cherry-laurel water acts in part as a gastric sedative, preventing the tendency to vomit which morphine produces in some patients. Where this tendency nevertheless exists I have given the morphine by suppositories or have substituted codeine, which must be given in doses four times greater than those of morphine, but is easy to administer, and little likely to produce gastric derangement.

With symptoms that from the beginning are chiefly local, it is but natural that local measures should have early occupied a prominent place in treatment. The local application of leeches, the use of blisters and other powerful counter-irritants have had their place and are now, happily, no longer relied upon. Not so with topical applications intended, by their temperature, to influence the course of the inflammation. Cold applications, hot applications, turpentine stupes, flaxseed or other poultices have had their champions, and are still very commonly used. It is sometimes difficult to decide what form of application may be best suited to the individual case, but it is a safe rule, in every instance, to consult the comfort of the patient, and to let that influence the selection of hot or cold applications. All of these applications are open to one serious objection, namely, that they require to be constantly changed—the cold applications, lest they get too hot, the warm, lest they grow too cool; and in these frequent manipulations the tender abdomen is liable to fresh injury.

It was formerly the practice in acute peritonitis, when mercury stood high in favor as the preliminary step in all kinds of treatment, to apply freely mercurial ointment to the abdomen, the ointment being spread upon flannel or some other soft fabric and left in contact with the abdomen. In the reaction following the excessive use of mercury the drug in all its forms was practically banished from the materia medica, save for a few specific purposes, and

this use of it in peritonitis was banished with the rest. But the pendulum has swung a little too far in the other direction, and, I think, we must again return to many of the things that were found useful by our fathers in medicine. For the last three years every case that has come under my care, in hospital or private practice, has been treated by the free application of mercurial ointment over the whole abdomen. It has promptly relieved the feeling of rigidity and painful distention; the immediate effect has been cooling and pleasant to the patients and the tympanites has subsided as quickly as after any other local application. It constitutes a dressing that easily adapts itself to the shape of the abdomen; it does not annoy by its weight; there is no wetting of the bedclothes, and the patient is not disturbed for its frequent removal, the ointment being renewed but twice in twenty-four hours. In all of these particulars it possesses decided advantages over other local applications. The mercury is evidently absorbed very slowly, for I have yet to see a case of ptyalism from its use; and in many instances it has remained in contact with the skin for two or three weeks.

Of the individual symptoms but two require especial mention in connection with the treatment, namely, the vomiting and tympanites. The former, which frequently ushers in the whole train of symptoms, is often so severe at the outset as to suggest intestinal obstruction; yet it is promptly controlled, as a rule, by large doses of opium. When occurring later in the disease, cracked ice taken freely into the mouth, small quantities of iced champagne, alone or in combination with aromatic spirit of ammonia, or half-drop doses of creasote in emulsion of sweet almonds, usually succeeds in controlling the trouble. Champagne has the advantage of being a stimulant and at the same time a gastric sedative; it is readily taken by children as well as by adults, and its use can be continued through the entire course of the disease.

Tympanites is always present to a greater or less degree but rarely, except in peritonitis of septic origin, and especially in those forms incident to the puerperal period, does it become excessive. The abdominal distention may, however, attain such proportions that the upward pressure of the diaphragm becomes a dangerous impediment to the circulation and respiration, and calls for immediate relief. A rectal tube carried high into the bowel, and left there, may accomplish all that is necessary; but this result cannot be confidently expected, since the gaseous distention is found mainly in the small intestine. Under these circumstances it has been recommended to puncture the bowel with a hypodermic or aspirator needle through the abdominal wall. I cannot regard such a plan as wholly devoid of danger, and should resort to it only in extreme cases, selecting a needle of the smallest calibre to be found. It is true that puncturing a healthy bowel is a matter of very little moment, since the muscular layer quickly contracts about the minute orifice, thus preventing the escape of liquid or gaseous intestinal contents; not so when puncture becomes necessary as a curative measure. Is not the tympanites itself evidence of paralysis, or great loss of tone of the bowel; and would not the increased pressure within the intestine tend to favor the escape of some of the intestinal contents as soon as the needle is withdrawn? Such considerations call for the exercise of the greatest care and discrimination with regard to this step.

The diet should be liquid, easily assimilated, and of a kind likely to leave but little residue. Some form of peptones, or peptonoids, now readily obtained, or, if need be, prepared by artificial digestion, constitutes at once a palatable drink and a food. A little alcoholic stimulant, brandy or whiskey, may be added from the first, and will help to sustain the patient. There should be plenty of fresh air, with a limited number of attendants. Above all I would enforce rest and quiet; and the constant stream of visitors that besets so many a sick-room is to be wholly interdicted.

I have made no reference to surgical measures, because I have been here dealing with what is known as acute idiopathic peritonitis, and surgical treatment is never called for in this disease, unless the case ends in abscess or diffuse suppuration. But with prompt resort to the treatment as here outlined such a termination is unlikely; and even in many of the secondary forms, occasioned by typhlitis or perityphlitis this treatment will obviate the necessity for an operation, which, however brilliant its results, is yet a very grave step for the patient, and not to be undertaken rashly. Despite the almost reckless manner in which the peritoneum is now treated by surgeons, we have the opinion of so brilliant and renowned an operator as Schede, advising against surgical intervention in peritonitis, simple or acute, and in perityphlitis during the height of the process, unless it can be pretty clearly shown in the latter case that perforation and a distinct tendency to sacculation exist.

The treatment of chronic peritonitis need occupy us but briefly. It may, indeed, well be questioned if such a disease as chronic peritonitis ever occurs, excepting that due to tubercular or cancerous infiltration. In both of these conditions supporting treatment, fresh air, good hygienic measures, and, in case of tubercular disease, the selection of a suitable climate, indicate the extent of the physician's power.

In cases of tubercular or cancerous peritonitis it frequently becomes necessary to interfere, by surgical

means, owing to great distention of the abdominal walls by fluid effusion. The operation of tapping is the classic remedy for this condition, but abdominal section, in the tubercular variety, seems to promise better results, as by means of it some cases have been cured. It is a question for pathologists whether these cases have really been tubercular in character, or whether the miliary nodules may not have been of the character of the tumors described as endothelioma, of which the peritoneum is the most frequent seat. At all events, we have not had records of every case successfully treated by incision, in which an autopsy subsequently revealed the return of the affection, nor can we understand from carefully-acquired knowledge of the life and habits of the tubercle bacillus how the mere exposure to the air for a few moments, and the contact with a warm solution of boric acid or plain boiled water, should permanently alter the conditions upon which its vitality depends. This question trenches, however, on the surgical aspects of the disease.

I am well aware that there can be no claim of novelty in the treatment here outlined, but it is sometimes desirable to burnish our old silver, and let the treasure appear in its true light.

THE EMPLOYMENT OF SPANISH MOSS (*TILLANDSIA USNEOIDES*) AS A SURGICAL DRESSING.

By LOUIS McLANE TIFFANY, M.D.,
PROFESSOR OF SURGERY IN THE UNIVERSITY OF MARYLAND, BALTIMORE.

The holding of raw surfaces in accurate apposition, the abolition of dead spaces, and the exercise of physiological pressure over a wounded area, are essential to rapid healing. To abolish dead space and exert the proper amount of pressure is not always easy and is largely dependent on the material used as a dressing. During the early spring of 1889, when on a plantation in Louisiana, it occurred to me that the moss which hung from the trees would be a soft and elastic wound-dressing, so I brought some home with me. I found later that it could be obtained in a sufficiently clean condition at any upholsterer's, and since the date mentioned I have continued to use it with great satisfaction.

The moss, which hangs in festoons from the branches of trees throughout the Southern States, is of the pineapple family—sub-order, *Tillandsia;* species, *usneoides*. Stems thread-shaped, branching and pendulous; leaves thread-shaped; peduncle short; one-flowered. (Gray.) On the trees it is of a gray color, very curly, and is prepared for commerce by being dried and beaten so as to free it from bark. After this process it appears to consist of black, elastic, tough fibres, resembling curled hair.

I usually have the moss made into cushions or pads of about six inches by four inches, and two inches thick, cheesecloth being the material employed as a covering. The pads have been made of other dimensions; in one or two cases of mammary extirpation with extensive axillary dissection, pads large enough to envelop nearly one-half of the thorax were employed, but I find no advantage in the use of such large cushions, and the size given has proved very generally applicable.

The pads are adjusted outside of a gauze-and-cotton dressing, and the bandage applied snugly, the elasticity of the moss serving to distribute the pressure evenly. About the chest wall, as after a deep axillary operation, I have been especially pleased with the pads. A fact of a good deal of importance is that when exposed to the action of moist heat in a sterilizer the moss remains elastic, so that the cushions are prepared with the other dressings for each operation.

AN ADDITIONAL NOTE ON THE EMPLOYMENT OF ANTIPYRINE IN PERTUSSIS.[1]

By J. P. CROZER GRIFFITH, M.D.,
INSTRUCTOR IN CLINICAL MEDICINE IN THE UNIVERSITY OF PENNSYLVANIA.

Two facts are to be prominently borne in mind in the employment of any drug in the treatment of disease. First, that no method of treatment is infallible, and that every drug will at times fail to produce the desired effect. Second, that success will sometimes depend on the adoption of *prudent courage*, and that a medicine should not be condemned as useless unless we are sure that it is the drug itself, and not the method of its employment which is at fault.

Soon after Sonnenberger's announcement[2] of the value of antipyrine in the treatment of whooping-cough, and stimulated thereto by his experience, I published[3] the reports of a number of cases treated in this way. Many of these proved that the drug is capable of exerting a very powerful influence upon the course of the affection. Since that time I have used the remedy in many cases, and usually with more or less improvement in the condition of the patient. In some instances the disease was favorably influenced in a remarkable manner, the paroxysms being greatly reduced in frequency, or in intensity, or in both. A large number of cases have been under my observation, however, in which this plan of treatment, now so generally in favor, was totally without effect, although as large doses were employed as I have, as a rule, found useful.

It has usually been my custom to begin the treat-

[3] Therapeutic Gazette, February, 1888.

ment with 2 grains of antipyrine, given every three hours, in patients two years of age, or from 3 to 4 grains at four years of age, and to increase this somewhat if necessary. These doses seem at first sight somewhat large, but it is, I think, certain that children bear drugs of the antipyretic series much better, and in much larger doses, than do adults, whether in febrile or afebrile states. I have never seen bad results follow these doses, and believe that much larger ones could sometimes be employed with advantage in bad cases. It is possible that some of the patients whom I have recorded as unyielding to this form of treatment would have been relieved by a more heroic dosage. At any rate, it is beyond dispute that many of those physicians who have reported adversely regarding the administration of antipyrine in whooping-cough have erred in the manner of administration. In a very severe and fatal endemic outbreak which occurred in an institution in this city within the past few years, infants received an amount which could only be considered useless, and as no fair test of the value of the drug. Of course, in the instance referred to it was without effect. Quite recently, in another local outbreak, children of from two to nine years of age were given only from 1 to 2 grains three times a day, and were, of course, entirely unrelieved by it; the remedy consequently being regarded as useless in the treatment of whooping-cough.

I am led to report the following case because several physicians of my acquaintance, who have had a large experience in the diseases of children, have failed to obtain satisfactory results from antipyrine in the affection under consideration; and the suspicion has arisen in my mind that the failure was, perhaps, due to an improper method of administration. The case is an instance of the advantage of a bold trial of large doses after small ones had proved useless:

Katie McD., four months old, only fairly well nourished and rather feeble, was brought to the Out-patient Department of the Children's Hospital, May 6, 1890. She was said to have been coughing for four weeks (although the exact time was uncertain), and was growing worse. It seemed that she was certainly approaching the height of the disease. The paroxysms were very frequent and very severe. As the child was evidently severely sick, and demanded vigorous treatment, this was commenced by giving ¾ grain of antipyrine every three hours; although this dose was so much larger than I had been in the habit of giving at this age, that I confess I was somewhat anxious lest the amount should prove injurious.

May 10. The child was no better, and was now having attacks of intense cyanosis and loss of breath after the paroxysms. These were so severe that the mother feared the child might die in one of them. As the antipyrine seemed to have failed to relieve, and as the mother was prejudiced against it, my assistant in my absence replaced it by extract of belladonna ¼ grain, alum ½ grain, whiskey 30 drops every three hours.

19th. The attendant at the clinic rushed excitedly into the room, followed by the mother with the child in her arms. It had just had a severe paroxysm, and was, when seen, deeply cyanosed, entirely unconscious, and with its head hanging forward on its chest. Respiration had entirely ceased. The child was in fact apparently dead, and I feared that it was actually so, for only after some moments could respiration be induced. The mother reported that the child had been much worse, and had been having attacks similar to, though probably not so severe as this, every quarter-hour or half-hour during the preceding night. She was evidently much feebler, and the prognosis was most unfavorable. In truth, I never expected to see the little girl alive again. Feeling that treatment had been absolutely without service, and that nothing but the most energetic and rapidly-effective remedies could save the life of the patient, I returned to antipyrine, increasing the dose to *1 grain every three hours*, believing that if the medicine did not kill the patient the disease certainly would.

21st. The mother returned to the clinic with the little patient lying quietly asleep in her arms. The thought arose that she might be too depressed by the drug, or by the exhaustion from coughing, to stir, but inquiry showed that her strength and liveliness were greatly improved. During the remainder of the day of her last visit, May 19th, the cough did not improve. On May 20th she was still coughing, but evidently with much less severity, for there were no attacks of cyanosis. During the night of May 20th the child *had not coughed at all* until five o'clock in the morning, and from that time until seen in the clinic (after 11 A.M.) *there had been no paroxysms whatever.*

28th. The medicine was administered until May 25th. The child then whooped about four or five times a day, and slept at night.

This case is, of course, a remarkable one, and such sudden and complete recovery from so desperate a condition will probably seldom be observed under any method of treating pertussis. The treatment was heroic, but necessarily so. Antipyrine given in doses of this size cannot be without danger, and such doses are not to be generally recommended. Nevertheless it seems hardly questionable that in cases of life or death it is better to dare than to watch inactively our patients die. That large doses of antipyrine will save the life of every patient with whooping-cough is not to be expected, but that it may be of the greatest benefit to some is proved by this case. The drug may be expected at least to mitigate the intensity or the frequency of the paroxysms in a considerable proportion of cases. I have known it relieve children who were rapidly losing ground on account of inability to retain sufficient food to nourish them, and to relieve them to such

an extent that they promptly regained strength. In some instances, as in this, the disease, while in the full vigor of the second stage, was either entirely, or almost entirely, checked. The administration of the remedy should be commenced in full doses and gradually increased, bearing in mind that though depression, and even collapse, may occur, yet the probability of these is exceedingly slight in afebrile cases as compared with the danger of it in febrile conditions.

TIN PLATES IN THE TREATMENT OF INDOLENT ULCERS.

BY E. R. MORAS M.D.,
OF CEDARBURG, WIS.

ULCERS are perhaps the most tedious and unsatisfactory cases in minor surgery that the physician is called upon to treat. Although this applies more particularly to varicose ulcers of the leg, yet one meets with ulcers in other localities, and of different origin, which are very difficult to heal, such as many of the ulcerated surfaces remaining after freely-incised septic wounds of the hand, arm, foot, or leg, after suppuration following amputations, and, in fact, after any wound, accidentally or intentionally inflicted, in which the granulations from lowered vitality of the tissues fail to cicatrize.

The various methods of treating indolent ulcers, and the remedies used both in and out of the profession, are surely too numerous to mention, but they can be generalized thus:

1. The moist treatment: Ointments, pastes, washes, wet antiseptic dressings, etc.

2. The dry treatment: Iodoform, iodol, boric acid, oxide of zinc, bismuth, and other powders.

3. Compression: Flannel bandages, rubber bandages, adhesive plaster, and silk elastic stockings.

These may be considered the usual methods. In addition rest of the part is sometimes enforced.

4. Skin-grafting: Small grafts repeatedly applied, or large grafts, after the method of Thiersch.

5. Transplantation of a flap.

6. Tin-plate treatment.

The latter mode of dealing with ulcerated surfaces is probably a novel one to many, and in this paper the writer will claim that in ulcerated wounds, which do not heal kindly, the tin-plate treatment is more certain, more satisfactory, and less tedious, and effects quicker results, than the first three methods of the foregoing summary, and that it is much simpler and more generally applicable than the fourth and fifth methods. And this is claiming only what is proven by facts. Of the cases which were thus treated I will report two—one a hospital case, the other a case in private practice:

CASE I.—L., a man aged about fifty years, who I saw a year and a half ago in the Cook County Hospital, Chicago. He was the first patient on whom the experiments were conducted. Each leg was the seat of an extensive, irregularly-shaped, foul ulceration, the results of a burn received two years before. One ulcer covered nearly one-third of the leg between the ankle and the knee. All forms of treatment had been tried for two years. To judge better of the effects of the tin plate I applied it over only a portion of one ulcer, selecting for the purpose the least promising one, situated over the inner aspect of the tibia. The remainder of the ulcer was treated with powdered iodoform. Four days later the dressings were removed, and the difference between the granulations covering the area over which the tin plate was used and those on the remaining surface was surprising. The former were smoother, cleaner, and healthier in appearance.

I now applied the plate over the entire surface of both ulcers. One week later the dressing was renewed, and an addition of one-fourth of an inch of new epidermis around the ulcer was found. Intervals of nine and ten days elapsed between this and the next two dressings, and finally the plate was left on for two weeks twice in succession. The smaller ulcer was then completely healed, and of the other a spot scarcely as large as a silver half-dollar remained. Satisfied that this would heal in a week or two, the patient asked to have the tin plate reapplied, and to be given his discharge.

CASE II.—A. L. received an injury to the left leg some twenty years ago, resulting in a chronic ulcer, which has since been almost constantly "running," and caused frequent disability. His occupation compels him to be on his feet during working hours.

When he submitted himself (which he did with great misgivings) to the tin-plate treatment, the leg was decidedly œdematous, excruciatingly painful at the ankle, and presented two scooped out, gangrenous ulcers, measuring respectively $1\frac{4}{5}$ by $1\frac{1}{4}$ inches, and $1\frac{1}{4}$ by 1 inch.

Simple washing with a 1-to-1000 bichloride solution was used, and the tin plate applied—the patient going to his work as usual. Four days later the sloughs had separated, and were removed with ease, the base of the ulcers already showed signs of activity, and their margins revealed a faint attempt at epidermization. In five more days the bases had attained the level of the skin, a decided growth of skin had taken place, there was but little œdema, and the pain had entirely disappeared. The dressings were subsequently renewed every sixth or seventh day, and both ulcers were found completely healed by the fifth week, the patient having lost not a single day of work.

REMARKS.—In the first case, ulcers which for two years manifested no inclination to heal under other forms of treatment disappeared under the use of the tin plates, and the time occupied in healing (about two months) was short enough to meet the most sanguine expectations. I may here remark that in this case Thiersch's method would have been at least partly a failure, owing to the condition of that

portion of the ulcer corresponding to the inner aspect of the tibia, for there could be no hope of grafts "taking" upon that area until some means had been devised to cover it with fresh, healthy granulations.

In the second case healing progressed without interruption *while the patient followed his usual avocation.*

From both of these cases we may infer that no operative procedure is required, and the annoyance of frequent dressings may be done away with.

Now, as to the details of the treatment. Bichloride of mercury solution, 1-to-1000, oiled silk or rubber-tissue protective, common sheet tin, surgeon's adhesive plaster, dressing material, and bandages, are required.

FIG. 1

With ordinary strong shears cut a piece of tin corresponding to the shape and size of the ulcer, but large enough to overlap one-fourth of an inch of the surrounding skin. Slightly evert the sharp edge of the plate, and cut a piece of oiled silk or rubber-tissue protective, of the same size. These are placed in the bichloride solution. The ulcer and surrounding surface are washed with bichloride solution; the protective is then placed over the ulcer, the tin plate over the protective, and firmly fixed with adhesive strips. Be careful that the plate is adjusted with uniform pressure.

It is best not to encircle the part with the strips of plaster, which would interfere with the circulation, and, as happened in my first case, produce a new wound by the adhesive strips cutting into the integument. As a rule, only a light dressing, such as one of gauze, is necessary, for when the secretions are profuse the patient himself may be allowed to renew the outer dressing every second day, and wash away the offensive discharges surrounding the tin plate with plain warm water, or an antiseptic solution.

No preparatory treatment of the ulcer is needed, unless the granulations are unusually elevated above the skin, when they may be levelled by one application of lunar caustic.

The primary dressing should be renewed on the fourth or fifth day after its application. Owing to the effects of the pressure the ulcer may seem larger than before, and, according to the former character of the granulations, it is found covered with a thin layer of creamy exudate or with a layer of slough. Even if the ulcer was formerly very indolent, it will already show signs of physiological activity; new, healthy granulations will be seen here and there, and on close observation a narrow border of very delicate

FIG. 2.

bluish-red epidermis may be seen creeping over the periphery of the wound, while the skin immediately surrounding it appears whitish and spongy. The same process continues between subsequent dressings, the granulations assuming a healthier appearance and activity, and epidermization advancing more rapidly.

When the ulcer is entirely healed it is advisable to reapply the tin plate for a week longer, that the delicate centre may have protection while it is becoming firmer. In cases which require it an elastic stocking of flannel bandage should be worn during the day as long as necessary.

The same piece of tin is used throughout the treatment, and is trimmed to meet the requirements of the varying size and shape of the ulcer. The first two, or possibly three, changes of the primary dressing are made at intervals of four or five days, after which it will seldom be necessary to change oftener than every eighth, ninth, or tenth day.

The good results will vary with the care and judgment used in fitting and fastening on the plate. Apply it snugly, and in such a way that the movements of the part will not displace it. Be careful that the edge of the tin is properly everted.

The tin and oiled silk, or rubber-tissue, might be perforated. I used them thus in the hospital, but not often enough to notice any special benefit resulting therefrom.

Were I to state the varieties of ulcers in which this plan of treatment gives the most satisfactory results, I would say that in varicose and other ulcers of the leg, in ulcers about the feet, hand, arm, and in amputation-stumps, it has given satisfaction.

The *modus operandi* of the tin plate in promoting the healing of indolent ulcers, which I have outlined for myself, may be an incomplete one. Some of the peculiarities of these ulcerations are: (1) That the granulations are raised above the level of the adjoining skin, which cannot creep over them; or, (2) the granulations are depressed below the skin, and lack the vitality necessary to fill the hollow; or, (3) they are constantly bathed in a profusely foul discharge; or, (4) they are wanting in the proper stimulation that would enable them to accomplish their physiological purpose. It would seem that the tin plate remedies these defects in two ways, namely, as a stimulant and as a compressor. Being a smooth foreign body it acts as a gentle stimulant, and, by compression, it prevents profuse oozing, and keeps the granulating surface to the exact level of the skin, or the skin to the level of the granulations, and thus affords the epidermis an opportunity to spread over the ulcer.

TWO CASES OF PROSTATECTOMY.

By J. WILLIAM WHITE, M.D.,
PROFESSOR OF CLINICAL SURGERY IN THE UNIVERSITY OF PENNSYLVANIA; SURGEON TO THE UNIVERSITY AND GERMAN HOSPITALS.

Dr. Belfield's original operation, followed by Mr. McGill's admirable work in the removal of portions of the prostate in those cases in which catheterization has become impossible, or has ceased to give relief, and in which cystitis has developed and septicæmia or uræmia is imminent, have attracted the attention of surgeons everywhere, and vastly increased the number of cases submitted to similar operative procedures. It is, therefore, of special importance at this time that all such cases, with their results, favorable or unfavorable, should be published, in order that we may arrive, as soon as possible, at some definite conclusion as to the indications and contra-indications, as well as to the scope and limitations of this operation, so exceedingly important on account of the large number of men who are the subjects of prostatic hypertrophy, and because in aggravated cases the suffering is so great and the disability so complete. For these reasons I desire briefly to place upon record the following cases:

Case I.—I. S., aged sixty-eight years, white, a hotel-keeper; family history of tuberculosis; always a moderate drinker, recently intemperate. Urinary symptoms began sixteen years ago; catheter has been required at intervals for eight years; for four years he has been unable to urinate at all without catheterism. Pain in hypogastrium has been progressively increasing until now it is constant and excruciating: pain is also felt at the end of the penis and in the rectum. He has lost flesh rapidly, having gone down from about 170 pounds to 120 pounds. Is sallow and pinched in appearance; has chronic bronchial cough: eats and sleeps poorly. Urine scanty (20 ounces in twenty-four hours) and loaded with pus and vesical débris; contains hyaline and granular casts. Physical examination *per rectum* reveals a prostate enormously enlarged both laterally and longitudinally, the finger being unable to reach its upper limit. The bladder contains a soft phosphatic stone of medium size. Mitral murmur of heart; bronchial catarrh, with evidence of beginning consolidation at left apex.

The case seemed very unfavorable, but the patient's suffering was so great, and his condition so steadily deteriorating, that it appeared to be justifiable to run considerable risk in attempting to relieve him. An operation for the removal of the calculus at least was clearly required. Litholapaxy was slightly contra-indicated by the intense cystitis which existed, and by the probability of recurrence, as the calculus was phosphatic, and strongly by the fact that the retention would remain unrelieved. Perineal lithotomy was negatived on account of the size of the prostate, and because of the very insufficient digital exploration of the bladder which it would permit.

Suprapubic lithotomy was therefore decided upon. The question of further operative interference, in case it was found practicable, with the object of removing the obstruction, was then submitted to the patient, with a fair statement of the attendant risks, which he promptly decided to accept.

The patient was carefully prepared by rest in bed, milk diet, attempted sterilization of urine by boric acid administered both by the mouth and by vesical irrigation, full doses of quinine, etc. At the time of operation the bladder was rendered accessible and opened in the usual manner. An oval rectal bag was used, and filled with eight to ten ounces of water. Ten to twelve ounces of warm boric-acid solution were injected into the bladder, which was reached by a linear incision three and a half inches long just above the pubes. The walls were transfixed with silk threads held by an assistant. The stone, which lay in the bas fond, crumbled down under the touch of the forceps, and had to be removed by the finger and a scoop. It was then found that both the middle and lateral lobes were greatly enlarged and projected far into the bladder. The mucous membrane at places was snipped through with scissors, and the major portions of the projection removed by enucleation with the finger.

This required the exercise of only moderate force, and was not attended by any considerable hæmorrhage. The pieces removed, eight in number, varied in size from a hickory-nut to a large walnut, and weighed three ounces. A large drainage-tube was inserted into the bladder and held in place by a stitch through one wall of the wound. A suture was inserted at each angle. The patient was returned to bed, with the wound dressed, fifty-five minutes after the incision was made, some delay having been caused by the difficulty in extracting the fragments of calculus from the deep parts behind the prostate. He was moderately, but not dangerously, shocked, and in ten hours had a normal temperature and a pulse of 100.

For three days the outlook was most favorable. There was not a single alarming symptom. The temperature reached 100° once on the second day, but fell again to normal, and subsequently was normal throughout with the exception of a few hours on the fourth day, when it again rose to 100°. Milk was taken freely, the patient was rational and comfortable. About the middle of the fourth day, however, he suddenly developed a maniacal delirium with excessive restlessness, wakefulness, jactitation, etc. He obstinately refused food, took off dressings when he had an opportunity, and had to be kept in bed by force. His tongue became dry and dark, and his pulse increased in frequency, but there was neither chill, sweating, nor rise of temperature. The urine continued to flow from the wound, which was irrigated daily with boric acid, with listerine, with phenol sodique. Various sedatives and hypnotics were used without effect, attempts at stimulation were equally useless, and the patient finally passed into a condition of stupor and died seven and a half days after the operation.

The following are the notes of the autopsy: Man, five feet seven; emaciated, pallid. Wound, two and one-half inches long in the linea alba, extending upward from symphysis pubis. Walls healthy, granulating. Genito-urinary organs and rectum removed together. Bladder shows granulating surfaces where portions of prostate were removed, but these are much smaller and much less noticeable than might have been expected. Lower portion of prostate and wall of bladder intact. No injury to recto-vesical septum or to urethra. No other foci of suppuration or ulceration present. Bladder capacious and moderately hypertrophied. Ureters distended to nearly the size of the wrist. Kidneys almost completely disorganized, containing multiple purulent collections, showing scars of previous abscesses, and rendered almost useless by chronic nephritis, scarcely any secreting structure remaining. Abdomen, organs healthy. Thorax, tubercular changes in both lungs. Cranium not opened.

REMARKS.—As I look back upon the case I may make the following criticisms of my own course:

1. It would have been wiser in the presence of scanty urine, tube-casts, and rapidly-increasing emaciation, and with a history of sixteen years of obstructive disease, to be content with supra pubic lithotomy and permanent drainage. In only one of Mr. McGill's twenty-four cases had the symptoms extended over sixteen years or more. In that case only a portion of the prostate the size of a pea was removed, the patient was not much relieved at the end of six weeks, and his further history was not traced. The next case in order of duration of symptoms had extended over fourteen years. Three portions the size of a bean were removed. The patient died the following day. His kidneys were healthy. None of the other cases approached these in length of continuance of urinary symptoms. It may certainly be assumed that the possibility of the existence of serious disease of the urinary tract above the bladder increases in every case in a direct ratio with the duration of obstructive disease anterior to that organ. Indeed, we know that even frequency of micturition is of itself a competent cause of ureteral dilatation, hydro-nephrosis, etc., and when to these factors are added such grave vesical changes as occur in these cases, it becomes a matter of astonishment that healthy kidneys are ever found in these patients.

2. I should probably have used chloroform instead of ether in view of the renal disease which I knew to exist, and which might have been fairly supposed to be extensive. It will be noticed that death did not occur from any form of septicæmia or pyæmia. It was undoubtedly uræmic, and it may have been hastened or precipitated by the employment of 10½ ounces of ether, many of the recorded ether-deaths having occurred in patients with chronic nephritis.

3. After the prostatectomy was decided upon and was begun, I might perhaps have been content with a much less thorough and extensive operation. Just here is emphasized the need of a large collection of similar cases reported in considerable detail, such as is now being made by Dr. Belfield.[1] I did not know then how much of the projecting prostate it was necessary to remove to insure subsequent spontaneous evacuation of the bladder. The risk of hæmorrhage, of shock from prolongation of the operation, of septic trouble from a larger absorbent surface, are all directly increased with the amount of the prostatic overgrowth which is removed, and it will be quite important in the future to know how little we may do with a reasonable prospect of resulting benefit.

In none of Mr. McGill's cases, where the weight of the portions removed is given, did it reach three ounces. In one both lateral lobes were removed in seven pieces, weighing two ounces and thirty grains.

[1] Since writing the above, Dr. Belfield's summary of cases has been published, and cannot fail to help us greatly in the attempt to arrive at definite conclusions as to the indications for and the value of the operation.

The patient died some months later. In another the piece removed weighed two ounces and forty grains. The patient died in thirty hours. We have not even now enough cases to generalize from, but it is significant that of the three deaths in Mr. McGill's table directly due to the operation, one was in a patient who had had symptoms for fourteen years; two underwent the removal of *large* portions of the prostate; and all three had bladders with thickened and hypertrophied walls. It is probable that we will find in these facts a valuable guide to our future work in this direction.

Case II.—A year ago, discovering a small, hard stone in the bladder of a gentleman sent to me from a neighboring city, I advised median lithotomy. The patient was forty-three years old; had been a free liver; came from a gouty family; had had gonorrhœa twice in his youth, and with one case had an attack of acute prostatitis as a complication. He had a urethral stricture, calibre 23 French (normal calibre about 32), four and one-half inches from the meatus. His urinary symptoms had for years been referred to that, and he had never before been examined for stone. On introducing the vesical sound I had some difficulty in passing it through the prostatic urethra, but as he was hyperæsthetic and very nervous, I was not clear as to the cause. Examination *per rectum* disclosed a prostate which I noted at the time in my case-book as "very moderately enlarged, but distinctly indurated." His urine showed quantities of pus and phosphates and oxalates in great excess, but there were no tube-casts. I advised lithotomy on account of the existence of the stricture, the presence of the cystitis, and the hardness and small size of the stone, which was presumably a mulberry calculus. Measurement by introduction of a very small lithotrite (child's size) showed that the stone was not more than a half to three-quarters of an inch in diameter, and confirmed the impression of its density given by the sound. The passage of the lithotrite was likewise difficult, gave rise to extreme pain, and was followed by profuse bleeding—facts which also influenced me in my selection of lithotomy, the small size of the stone leading me to choose the median variety of that operation.

A few days later, after the usual preparatory treatment, I cut him at his home. As the knife passed from the membranous to the prostatic urethra I remarked upon the almost cartilaginous density of the tissue through which I was cutting, and upon the great increase of the "perineal distance"—the distance from the junction of the membranous and prostatic urethras to the most distant point of the median enlargement within the bladder.[1] This distance, I should think, was not less than three and one-half inches, and it was only by having the hypogastrium strongly depressed that I could reach the bladder with the tip of my middle finger. A small pair of forceps was introduced, and after a little difficulty the stone was caught and extracted. Further digital exploration showed that the middle lobe of the prostate was enlarged, distinctly pedunculated, and projected directly upward. I seized this projecting portion, which was really intravesical, first on one side of my incision and then on the other, with strong forceps, and by dissection with my finger-nail, and by dragging and twisting strongly with the forceps I succeeded, with some trouble, in removing two small particles, each the size of a hickory-nut, and looking to the naked eye, and on section with the knife, not unlike scirrhous carcinoma. As the patient bled freely, and the separation of the fragments required the use of so much force, and as I had not discussed with him or his family the propriety of any operation except that of lithotomy, I decided to refrain from further interference. I did so, however, without much hope of having given him permanent relief from his urinary symptoms.

The specimens were submitted to Dr. John Guiteras, Professor of Pathology in the University of Pennsylvania, who reported the growth as "a pure fibro-myoma with no admixture of suspicious elements of any sort." The patient convalesced without a bad symptom, and was out of bed with the wound healed in two weeks. He was in my office within a few days on account of a recent urethritis, and reports himself as free from all vesical symptoms.

Remarks.—In this case, as I saw the patient but once before the operation, I neglected to inquire into the existence of residual urine. The absence of any lateral prostatic overgrowth, as revealed by rectal touch, prevented me from attaching much importance to the prostatic hardening which I did feel. The difficulty in the introduction of instruments seemed sufficiently explained by the great sensitiveness of the patient and by possible urethral and prostatic spasm dependent on the stricture and the calculus. If it had not been for these circumstances I would doubtless have discovered the prostatic growth earlier, as I was, of course, aware that intravesical growth sufficient to cause marked urinary symptoms frequently exists without any appreciable enlargement toward the rectum. I am not at all sure, however, that such a discovery would have been to the advantage of my patient. If a prostatectomy in addition to a lithotomy had entered into my calculations I would probably have selected the suprapubic route for the performance of both operations. Indeed, after having made the median incision and discovered the depth of the perineum I would have been justified, according to excellent authority,[1] in employing hypogastric section and cystotomy then and there. I could by no possibility, however, have had a better result.

Perineal prostatectomy as an accidental or inter-

[1] Watson: The Operative Treatment of the Hypertrophied Prostate.

[1] Watson: loc. cit. Belfield: American Journal of the Medical Sciences, November, 1890.

current complication of perineal lithotomy has been known since the days of Fergusson, and has never had a large mortality. Its usefulness, however, is confined to the class of cases like this one, in which the obstructive cause consists of an enlarged and pedunculated middle lobe. The other varieties described by McGill (and by Brodie, Cadge, Thompson, and others before him), viz, the collar enlargement, the hypertrophy of the lateral lobes, or of either of them alone, or the hypertrophy of all three lobes, are unquestionably to be dealt with most satisfactorily by suprapubic cystotomy; but it must be noted that the latter operation has a mortality of 16 per cent. as against 9 per cent. by the perineal method.[1] It seems to me that one explanation of this fact lies in the comparatively moderate interference with the prostate which this method permits of. I feel sure, at any rate, basing my opinion on general surgical principles, that some of the recent teaching on the subject touches too lightly on the increase of danger which must necessarily be associated with more extreme removals of portions of the prostate. Belfield, speaking of the possibility of return, says, for example:[2] "An important deduction from these considerations is the indication for thorough enucleation of all circumscribed masses within as well as above the general prostatic surface. Such tumors can be enucleated with surprising rapidity." "An important advance in the removal of prostatic obstructions is the enucleation of all accessible masses in the substance of the organ instead of a simple levelling off, etc." McGill[3] and Mayo Robson[4] write in the same vein. I believe in the future of the operation, and think that in carefully-selected cases it is likely to have a progressively smaller mortality, but I do not think it one to be undertaken lightly, and I am quite sure that it is not proper to adopt it as a routine method of treatment in all prostatics.

A considerable proportion of patients with obstructive prostatic enlargement can be made perfectly comfortable by the use of a Nélaton or Mercier catheter, provided the instrument is scrupulously sterilized before and after each introduction. It should be employed by the patient himself from one to three times daily, according to the amount of residual urine. Such patients may go on for years in this manner with little or no difficulty, and do so with increasing frequency since the importance of urinary antisepsis has been realized and its details perfected. In spite of every precaution, however, a number of cases break down, the catheter cannot be passed without distress, or without causing troublesome bleeding, or occasionally cannot be passed at all. The urine becomes ammoniacal and stinking. Vesical tenesmus is constant and severe. These are the symptoms which, above all others, indicate the performance of prostatectomy, viz., difficult and painful catheterization and the occurrence of marked and persistent cystitis.

In the presence of those symptoms, in a person of average strength and vitality, the surgeon should, in my judgment, proceed in one of the two following ways:

First: Introduce Syme's staff into the bladder, and make a small incision through the perineum and the membranous and prostatic urethra. Introduce the finger into the bladder. If a pedunculated middle lobe is found, enucleate it with the finger, or twist it off with forceps, as in the above case. Put in a large drainage-tube, and allow it to remain for a week or two.

Or, second, make a suprapubic cystotomy, remove only such portions of the prostate as are manifestly obstructing the urethral orifice, and then if the urethra is not free complete the operation by doing an external perineal urethrotomy.

Statistics are not yet numerous enough to allow us to be dogmatic as to the relative merits of these plans, but I am inclined to think that in the majority of cases the second is the one to be preferred.

In cases markedly feeble, and especially in those with chronic nephritis, it is best to be content with establishing perineal drainage.

HOSPITAL NOTES.

CYSTITIS.

Abstract of a Clinical Lecture delivered at the Chicago Policlinic.

BY WILLIAM T. BELFIELD, M.D.,
PROFESSOR OF SURGERY.

DR. BELFIELD presented six cases which were sent to him with the diagnosis of cystitis, but which illustrated the fact that cystitis is a secondary affection, and that therefore the first step in the treatment must be a search for the cause, that is, the primary morbid process. We should remember, he said, that cystitis is—like jaundice and dropsy—a result, a symptom of disease, and not the primary disease itself; and that the cause of the trouble may be found anywhere in the urinary tract from the meatus to the capsule of the kidney.

CASE I.—A robust man, twenty-one years old, who had had for the past six months gradually-increasing frequency of, and pain during urination. He now evacuated the bladder every hour, day and night, the act being accompanied with pain along the entire urethra. On standing, the turbid urine deposited a slight amount of pus.

Examination excluded morbid conditions of the meatus and prepuce, stricture, and stone. The right epididymis presented, however, a hard, painless swelling, in places distinctly nodular, a condition which the patient

first noticed nearly three years ago. This swelling was evidently tubercular, and gave a clue to the cause of the cystitis, the tuberculous process having doubtless found a foothold at some point in the genital outlet near the bladder.

Upon rectal examination a distinct hard thickening near the right seminal vesicle at the apex of the prostate was found. The process probably extended to the vesical surface of the prostate, where it could be recognized by means of the cystoscope.

CASE II.—A man, fifty-five years old, whose symptoms dated back one year. After the patient had urinated Dr. Belfield introduced a soft catheter and withdrew one ounce of residual urine. Rectal examination showed an increased vertical diameter of the prostate. This case was evidently one of chronic retention from prostatic obstruction.

CASE III.—A man of thirty-five years, with a history of cystitis for three years. Examination of the pelvic and external organs was negative, but a hard painless body was discovered just below and adjoining the right kidney. The disease was tuberculosis of the kidney, and illustrated the fact that symptoms of cystitis are frequently produced by morbid conditions of the pelvis of the kidney.

CASE IV.—A boy of nineteen years, who was sent to Dr. Belfield eight weeks previously with the history that for six years he had usually been obliged to urinate at least once every hour, though occasionally enjoying a respite for a few days. His urine contained a small amount of pus. A sound entered the urethra to the prostate without obstruction, but was stopped in the prostatic urethra, as determined by the finger in the rectum. No instrument could be made to enter the bladder except a small flexible bougie. Perineal urethrotomy was performed, and the obstruction found to be a hypertrophied prostatic ring (internal sphincter), an unusual condition in young men. The body of the gland was not enlarged. The constricting ring was thoroughly stretched with forceps and with the operator's fingers.

The patient stated that since the operation he has been able to retain his urine for from three to five hours without discomfort, and has gained fifteen pounds in weight and feels perfectly well.

CASE V.—A man of twenty-seven years, who had had the usual symptoms of cystitis, associated with considerable aching in the perineum, for two years. Dr. Belfield said that the last symptom suggested the condition which, upon examination, was found to exist, namely, chronic inflammation of the posterior urethra. During the last month he had given the patient twelve deep injections of nitrate of silver solution of a strength of seven grains to the ounce. The symptoms have almost disappeared.

CASE VI.—A man of forty-three years, of full habit, who for three years had been treated by different physicians by nearly all the usual remedies for cystitis, both local and general. After a careful examination some three months ago, Dr. Belfield suspected a calculous pyelitis of moderate extent. Treatment with the object of relieving this produced, however, no improvement, but within two weeks an attack of severe renal colic occurred, and was followed by the expulsion of three uric-acid calculi—the largest of which was about the size of a bean. Complete recovery from the "cystitis" ensued.

MEDICAL PROGRESS.

Treatment of Gastric Ulcer.—DONKIN (*Wiener medizinische Presse*, November 2, 1890) thinks that the best results in the treatment of gastric ulcer are obtained by giving the patient neither food nor medicine by the mouth, and relying upon rectal alimentation. He does not believe that gelatin suppositories and peptonized preparations have any advantages over beef-tea and milk in rectal feeding. The patient should receive at intervals varying in different cases 2½ ounces of beef-tea and from ½ to 1 ounce of brandy either with or without the yolk of an egg. An equal amount of milk may be substituted for the beef-tea, or the enema may consist of equal parts of each. It is necessary to wash out the rectum before each injection and if it becomes very irritable a few drops of laudanum may be given with each enema. By the mouth, the patient may be occasionally given a small piece of ice but absolutely nothing else. Morphine, given subcutaneously to allay the pain, the author considers the most useful drug that we have in the treatment of gastric ulcers.

In Donkin's experience this treatment causes the gastric symptoms to disappear in from ten to nineteen days, when in addition to the enemata small quantities of milk and bouillon may be given by the mouth. The author has also adopted this method in the treatment of many obstinate cases of dyspepsia.

Guaiac as a Laxative.—MURRELL (*Medical Press and Circular*) thinks that guaiac is a valuable laxative. His attention was drawn to the subject, two years ago, by casually prescribing guaiac lozenges made up with black-currant paste, for a man suffering from rheumatism. The man continued taking the lozenges long after the pain had ceased, and in explanation said that they did him good by acting on the liver and bowels, and said that one or two of the lozenges taken in the morning before breakfast produced a stool promptly and without inconvenience. The author ordered the lozenges for others of his patients suffering from constipation, and what is conventionally called "biliousness," and the results were equally satisfactory. The lozenges not being available for hospital use, he had a confection prepared containing ten grains of guaiac resin to one drachm of honey. This, for the last two years, he has used extensively not only as a purgative, but in the treatment of chronic rheumatism, sciatica, tonsillitis, dysmenorrhœa, and allied affections. He gives from one to two drachms three times daily. The purgative effect is very pronounced, and in one case the patient had fifty-six evacuations in one week. In another case it produced a well-marked rash, covering the arms and legs with an eruption which forcibly reminded one of a copaiba rash. It was accompanied by intense itching which disappeared on discontinuing the drug. The guaiac not infrequently gives rise to a burning sensation in the throat, and to obviate this he prescribes ten grains of the resin in half an ounce of extract of malt. He believes that a trial of guaiac, either as a laxative or purgative, according to the dose employed, will be found satisfactory. It is possible that if

the drug were triturated with cream of tartar, or with some inert substance, such as sugar of milk, its efficacy would be increased, and that itwould produce the desired effect in smaller doses.—*London Medical Recorder*, November 20, 1890.

Iodide of Potassium in the Treatment of Urticaria.—Stern has successfully treated five cases of chronic urticaria by the administration of iodide of potassium, four of the cases having been rebellious to all the measures usually employed in this disease. The fifth case was one of acute urticaria of a few days' duration. None of the patients were syphilitic and all were rapidly cured. In one case which had lasted for four months the intolerable itching disappeared on the second day of treatment, and a complete cure was obtained after two and a half drachms of the iodide had been administered. In two other cases, one of two years' and the other of six years' duration, the effect of the iodide was equally good, cure following the administration of six and eight drachms respectively.—*London Medical Recorder*, November 20, 1890.

Somnal.—As a result of several experiments upon animals and fifty-four administrations to man Dr. W. Gilman Thompson (*New York Medical Journal*, Nov. 29, 1890) comes to the following conclusions:

1. The effects of somnal are much more striking and certain than those of urethan, and far less depressing than those of chloral.

2. There is no vertigo or depression after taking somnal, such as may follow the use of sulphonal.

3. The action of somnal is usually very prompt, and doses of half a drachm disguised in a little syrup of tolu or whiskey are always well borne, easily taken, and entirely without deleterious effects.

4. The drug in doses of a drachm is not powerful enough to control decidedly delirium tremens, maniacal delirium, or severe pain.

5. In doses of from thirty to forty minims somnal is a safe and reliable hypnotic for ordinary insomnia.

Creolin in Diseases of Children.—Schwenz has used creolin in the treatment of a number of infantile diseases. In ten cases of purulent ophthalmia in the newborn irrigations with a one-per-cent. solution were practised. In two of these cases in which the disease was not very intense there was complete cure at the end of six days. In the eight remaining cases irrigations were continued for four or five weeks but the results were not satisfactory, and recourse was had to solutions of boric acid and nitrate of silver. A solution of the strength of one or two per cent. of the latter was used by instillation and caused less pain than the creolin solution.

Eleven cases of thrush and aphtha which had been treated for a long time with potassium chlorate, potassium permanganate, and boric acid without appreciable results were cured by irrigations of the mouth and pharynx with one-per-cent. solution of creolin.

In cases of umbilical periphlebitis the use of an ointment of creolin was followed in four days by complete disappearance of the inflammation. The author also writes that the use of pure [?] creolin by friction will give gratifying results in the treatment of erysipelas.

In five cases of acute gastro-enteritis creolin was given according to the following formula, and caused the symptoms to disappear in from three to six days:

R.—Creolin . . . . . 3 drops.
Canella water . . . 2½ ounces.
Syrup of mallows . . . 6 drachms.

Dose for very young children, a small teaspoonful every hour. For older children the creolin may be given in powders thus:

R.—Creolin . . . . . 15 minims.
Sugar . . . . . 75 grains.—M.

Divide in ten powders and give one or two daily.

In the surgical diseases of children creolin, according to the author, may be used in the strength of from one-half to one per cent. to produce asepsis of the surface and cavities of the body without fear of poisoning.—*Archives of Pediatrics*, December, 1890.

Pambotano: a Substitute for Quinine.—According to *Le Progrès Médicale*, a decoction of pambotano, the root of the *Calliandra Houstoni*, is proposed as a substitute for quinine. Very few cases in which it was used have been reported, and it is impossible as yet to form any opinion of its value.

Application for Chronic Pharyngitis.—The *Canada Lancet* quotes the following prescription for the treatment of chronic pharyngitis:

R.—Ergotin . . . . . 15 grains.
Tincture of iodine . . 1 drachm.
Glycerin . . . . . 1 ounce.—M.

To be applied three times daily, with a soft brush.

Strophanthus in the Treatment of Exophthalmic Goitre.—In a paper read before the New York State Medical Association (*New York Medical Journal*, November 8, 1890), Dr. E. D. Ferguson reported several cases of exophthalmic goitre in which the administration of strophanthus afforded prompt relief, the patients being able to return to their ordinary occupation. As was expected, however, in no instance was either the exophthalmia or the goitre removed, although in each there was decided improvement. The pulse-rate and the rhythm of the cardiac contractions improved even in cases in which there was undoubtedly dilatation of the left ventricle, and in the latter cases all the signs and symptoms of dilatation disappeared. The only preparation of the drug used by Dr. Ferguson was the tincture, which was given by the mouth three times daily during meals, the initial dose being from eight to ten drops, which was increased, if necessary to reduce the frequency of the pulse, to fifteen, twenty, or even twenty-five drops.

Insoluble Tablets of Antipyrine.—According to Dr. Arnold, of Zug (*British Medical Journal*, October 4, 1890), many of the tablets of antipyrine, antifebrin, and other new preparations, pass through the alimentary canal undissolved. This fault is easily remedied by having a thin layer of powdered sugar or tragacanth interposed between the layers of the tablet. He advises that physicians from time to time test the solubility of these tablets by placing them in water.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author.

Address the Editor: H. A. HARE, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including Postage.

PER ANNUM, IN ADVANCE . . . . . $4.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

SATURDAY, DECEMBER 13, 1890.

DR. BILLINGS AND THE SURGEON-GENERALSHIP.

THE President of the United States is again called upon to fill the high office of Surgeon-General. The task is not an easy one, and we feel it our duty to speak briefly but strongly upon the question. From an early day the principle of seniority has been discarded in filling this office. Barnes and Crane were promoted over the heads of a considerable number of seniors, and we hold that it is essential for the good of the country and the service that this policy should be followed. The best man for the place should be chosen irrespective of seniority. The great scientific and sanitary questions which agitate the medical world to-day have important bearings upon the medical service of the Government, and may require a man who is thoroughly abreast of the times, and fully equipped with the latest attainments of science. The office is not wholly, or perhaps chiefly, a scientific one, however; the Surgeon-General has important executive and administrative duties as well. The general supervision of the great National Museum, and of the famous Library of the Surgeon-General's Office, and of the Government hospital system throughout the country, are among the matters which devolve upon him. He must have strict financial methods, and should be a man of business training and ability. He must be a good judge of men, and able to make his appointments so as to get the right men in the right places, and to get the greatest amount of work out of all of his assistants and associates. Our national medical service now enjoys a high reputation the world over, and it is the duty of the Government to make an appointment at the present juncture that will not only maintain, but enhance this good reputation.

For all the reasons above urged we hold it of the first importance that DR. JOHN SHAW BILLINGS should be named Surgeon-General. Born in Indiana fifty-two years ago, he was graduated from The Medical College of Ohio. He was graduated in medicine in 1860. He entered the army at the opening of the war and saw hard service, including the battles of the Wilderness. As an organizer and executive of hospitals he achieved an early and a high reputation. Under Surgeon-General Barnes he disbursed during eight years many millions of dollars with the greatest satisfaction to his superiors, and in the organization and development of the Library of the Surgeon-General's Office he has shown executive and administrative talents of the highest order.

It is needless to refer to the high position he has attained as an authority upon sanitary science. At the present time he is officially connected with Harvard University, the University of Pennsylvania, Columbia College, and Johns Hopkins University. He has received the highest recognition from abroad. Oxford, Cambridge, Edinburgh, and Munich have conferred honorary degrees upon him, and his career is full of instruction and encouragement to the profession. The special duty to which he has been detailed so long in Washington has not been used as a means of leisure or personal gain. No medical man in the country has worked harder, or to better effect, and the Government would honor itself by rewarding this distinguished man with the highest medical gift that is in its power to bestow. The President and his advisers may rest assured that no appointment they can make will be regarded so favorably by the Medical Corps of the Army and by the medical profession at large.

KOCH'S DISCOVERY.

SINCE our last issue a number of physicians in this country have received a supply of Koch's lymph, and will doubtless soon be ready to present to their professional brethren the results of their experiments. As already announced, Drs. Chittenden and Foster, of New Haven, were the first in the

field by some days, and they will be followed by Dr. Jacobi and Dr. A. McLane Hamilton, of New York, as well as by Dr. Bennett and a committee appointed by the University of Pennsylvania in Philadelphia. We are glad to announce that the reports of Professor Chittenden and Dr. Foster, Dr. Hamilton, and Dr. Bennett have already been secured for publication in The Medical News; and a number of other gentlemen who have just begun their work with the liquid have promised to contribute reports from week to week. Information derived from widely-separated sources, and obtained primarily by investigators thoroughly qualified to complete such studies, cannot fail to prove of interest to our readers.

In another column will be found a general summary of news concerning the character and effects of the fluid, which, while it conveys no definite information concerning the character of the liquid, shows the direction of thought in Europe in regard to its possible composition.

CORRESPONDENCE.

LONDON.

Koch's Treatment of Tuberculosis—A Case of Sleeping Sickness.

Koch's method of treating tuberculosis is still creating great excitement, and almost every day we see in the papers some fresh proof of the widespread desire for advertisement. Meanwhile the first reports of enthusiastic but utterly untrustworthy newspaper reporters have by no means been substantiated, for so far from cases of lupus being cured in a few hours and almost under the eyes of the observer, we have not been shown a single instance in which a cure was effected. That the new treatment exercises a most remarkable influence upon lupus there can be no doubt, for several medical men who have returned from Berlin agree upon that point, and I hoped that last night we who stayed at home would have an opportunity to see one of the cases, for it was expected that Mr. Malcolm Morris would exhibit at the Clinical Society the patient whom he took to Berlin three weeks ago. But it seems that the cure is not sufficiently advanced, and the patient is still there. As, however, Mr. Watson Cheyne and Dr. Heron have returned with some of the precious fluid, and have commenced inoculating patients, we shall not have to wait long before we can judge of the results.

A good deal of abuse has been vented upon the College of Physicians for not sending delegates to investigate the subject, but it seems to me that the College has taken the right position, for at present no facilities are given for investigation; and if such an investigation were permitted, I am by no means sure that the College of Physicians is the proper body to undertake it. The matter is of such great importance that, I think, the Government, and not private parties, should set on foot the inquiry. At present, however, Koch has declined to divulge his method, and although this is contrary to all scientific tradition, no one can compel him to do so. His ostensible reason for secrecy, namely, that incompetent persons would at once prepare a fluid which would not give the expected results, and so bring the treatment into disrepute, is clearly a mere excuse, because it will also apply whenever he does make public his mode of preparing the "brown fluid." The general belief here is that Koch is working at the cure of other infectious diseases on the same lines, and that he is afraid that if he now describes his methods someone will precede him in discovering a cure for the other diseases.

A fortnight ago Dr. Stephen Mackenzie showed a case of the so-called "sleeping sickness" of the Congo, at the Clinical Society. The patient was a negro, aged twenty-two years, who had spent all his life in the neighborhood of the Congo, and had come to England in order that his malady might be thoroughly studied, though not with any expectation of being cured. Nearly all of the members of his family have succumbed to the disease, and in the district where he lived it is well known and much dreaded, for it is believed to prove invariably fatal. As the name implies, a lethargic tendency is the chief characteristic, and is accompanied by progressive weakness. Dr. Mackenzie's patient has been under observation since June, and has had continuous fever. When he arrived he was able to go about and even do light work, but tremulousness gradually came on, and now he is so weak that he can do nothing. His mental powers have grown gradually weaker, so that it is difficult to get him to answer a question. He almost constantly falls asleep, but never sleeps long at a time, either during the night or day. One important feature in the case remains to be mentioned, and that is, the presence of filariæ in the blood. Contrary to the usual rule, these show no periodicity, and are always present—a fact that Dr. Mackenzie is inclined to attribute to the febrile condition. He is doubtful of any connection between the filariæ and the lethargic attacks, as filariæ have not been observed in other cases; but it must be remembered that very few cases have been carefully observed, and probably none so carefully as this one. The blood is, in other respects, normal, and the patient is not the subject of any form of malaria. The case is obviously progressing to a fatal termination, and the report of the autopsy should be of much interest.

PARIS.

The Production of a Biliary Fistula for Disease of the Liver—Sudden Death in Diseases of the Abdominal Organs—Intestinal Antisepsis—Observations on a Guillotined Man.

At the last meeting of the Academy of Medicine Professor Terrier reported an interesting case of exploratory abdominal section to ascertain the condition of a diseased liver. The history of the case is as follows:

The patient, a man, was admitted to the hospital with the diagnosis of hepatic cyst, but an exploratory puncture showed that there was no cyst, and the diagnosis remained obscure, there being intense jaundice with

clay-colored stools and general symptoms. Professor Terrier determined to open the abdomen. At the operation the liver was found enlarged and congested, but no tumor or calculus was discovered, either in the gall-bladder or ducts. Professor Terrier then determined to make a biliary fistula, and to do this he sutured the mucous portion of the gall-bladder to the abdominal parietes and made an opening sufficiently large to admit a No. 10 catheter. The results of the operation were excellent. Two days later the fæces were of a natural color, while the general symptoms gradually disappeared, and one month later the patient left the hospital with the biliary fistula still open. The liver remained somewhat enlarged.

Dr. Jacquemard has lately made a study of the cause of sudden death in cases of abdominal diseases. The results are of great scientific interest and are important from a medico-legal point of view. The mechanism of sudden death in certain abdominal lesions, such as cancer of the stomach, hepatic cirrhosis, and cancer of the liver and pancreas has heretofore been obscure. Some authors believe that it is the result of cardiac degeneration and consequent syncope; others believe that death in such cases is due to sudden reflex inhibition of the heart. The two following histories are interesting in connection with the subject:

The first case was that of a man, forty-five years old, suffering from carcinoma of the lower curvature of the stomach. He was not cachectic, and his general appearance was excellent; he had no marked cardiac symptoms except a murmur of the right heart. He died suddenly, and on post-mortem examination the tricuspid opening was found dilated—admitting three fingers. The cardiac muscle appeared healthy.

The second patient was suffering from interstitial nephritis of the right kidney, and also from tuberculosis of the right suprarenal capsule. He died suddenly during sleep after a few convulsive movements of his extremities. At the autopsy no lesions were found in the brain or lungs. During life the heart presented no abnormal symptoms, yet at the autopsy the parietes of the right heart were found in a state of myocarditis, the left heart being normal.

The cardiac lesions alone in these two cases, according to the author, were not sufficient to produce sudden death, which, he thinks, was caused by some abdominal reflex. The effect on the heart of a reflex starting from a sudden and prolonged irritation of the filaments of the solar plexus is without danger or gravity if the heart is healthy, but a sudden arrest of cardiac action is probable where there are lesions of the organ.

Professor Debove has presented before the Société Médicale des Hôpitaux a new mode of treating tubercular peritonitis. Spencer Wells, in 1862, opened the abdomen of a case of tubercular peritonitis believing he had to deal with an ovarian cyst. The patient, however, improved after the operation, and since then some surgeons have recommended opening and washing out the cavity for this disease. Dr. Debove, thinking that abdominal section could be dispensed with in such cases, simply tapped, in the case of a woman, aged twenty-eight years, who suffered from tubercular peritonitis, the diagnosis being confirmed by injecting the peritoneal fluid in three guinea-pigs which became tuberculous. As soon as the patient was tapped, the peritoneal cavity was washed out with a saturated solution of boric acid. Eight days later her condition had very much improved—she has gained twelve pounds, and is now considered cured.

At the Société de Biologie Dr. Féré recently presented photographs of a patient suffering from epilepsy treated by large doses of bromide of potassium, which greatly diminished the number and severity of the fits, but caused most serious cutaneous lesions. These lesions disappeared under the use of intestinal antiseptics—naphthol, associated with the salicylate of bismuth. In a number of similar cases Dr. Féré has seen digestive troubles disappear under the influence of the same treatment, permitting one to increase progressively the dose of bromide.

Dr. Gley has presented the results of his observations on a guillotined man whom he had the opportunity to study a minute and a half after death. The heart was flaccid, but still beating regularly. The anterior interventricular groove was mechanically excited by means of needles, which produced that state of the ventricles known as tremulation. The auricles after this excitation also presented tremulation; but, contrary to what took place in the ventricles, their rhythmical movements started again. After a second irritation the right auricle again showed tremulation, while the left auricle continued to beat rhythmically until the fourteenth minute after death. Dr. Gley has observed rhythmical contractions of the diaphragm even three-quarters of an hour after death.

Before closing this letter, let me give you two or three of the most common formulæ used in the Paris hospitals as intestinal antiseptics.

Professor Bouchard recommends the following in cases of gastric and intestinal fermentation as found in cases of gastric dilatation, in poisoning by decayed or diseased meats, in typhlitis, dysentery and typhoid fever, and in diseases in which there is insufficient renal secretion:

R.—Beta-naphthol, finely pulverized ½ ounce.
Salicylate of bismuth . . 2 drachms.—M.

Divide into thirty wafers, and give from three to ten daily.

Professor Dujardin-Beaumetz recommends the following:

R.—Pure bisulphide of carbon . 35 grains.
Essence of peppermint . . 30 drops.
Water . . . . . 15 ounces.

The mixture is placed in a large bottle, shaken, and allowed to settle: 8 to 12 tablespoonfuls are to be given daily in half a tumblerful of water and wine, or in milk.

Dr. Huchard recommends:

R.—Salicylate of bismuth
Salicylate of magnesium } of each 75 grains.
Benzoate of sodium —M.

Divide into twenty wafers, one of which is given before each meal.

ROME.

The Third Italian Congress of Internal Medicine.

The third annual Italian Congress of Internal Medicine was held this year at Rome between October 20th

and 23d. Several interesting papers were read, of which I will give a brief account.

The subject of the etiology and treatment of pleurisy occupied the first day of the meeting. Dr. Patella gave a short review of the present status of the subject. He said that ten years ago only three kinds of pleurisy were described—the rheumatic, the traumatic, and that due to extension of the inflammatory process from the lung. We have now also pleurisies of microbian origin. The sero fibrinous pleurisy is still considered as rheumatic, but another agent besides cold is necessary for its development. The cold probably prepares the organism for microbian infection by modifying the circulation in the blood and lymphatic vessels. The way in which germs penetrate into the pleura is still obscure, but Fränkel has demonstrated that one of the microbes of purulent pleurisy—the encapsulated lanceolated micrococcus—is found in the tonsils, and from there it may reach the pleura through the lymphatic channels. According to Ziemssen, certain pleurisies are not of microbian origin, such as, for instance, those appearing in acute rheumatism. A bacteriological examination of the products is often difficult, and some positively tuberculous pleurisies present no bacilli on examination. Maragliano states that a tubercular pleurisy can give rise to a serous effusion. On the other hand, Dr. Patella has observed non-tuberculous pleurisy in tuberculous patients, the pleurisy being due to Fränkel's diplococcus. The speaker concluded with the following summary: 1. There are sero-fibrinous pleurisies caused by Fränkel's encapsulated micrococcus. 2. There are pleurisies with extensive effusion, probably of tuberculous origin. 3. In tuberculous subjects, pleurisy of non-tuberculous origin may occur. 4. There also exist pleurisies of *chemical* origin, which are not yet understood. 5. It is safer to rely on clinical symptoms than on bacteriological examination to determine the causes and nature of primitive pleurisies. 6. The etiology of pleurisies secondary to acute pulmonary inflammation, meta-pneumonic pleurisies, is certainly that of the pneumonia. Their prognosis is generally more favorable than that of primitive pleurisies. 7. The spontaneous absorption of pus in cases of purulent pleurisy is possible when the pleurisy originates from Fränkel's diplococcus, and whenever this microbe is found we are justified in expecting a cure.

Dr. Luzzato, of Padua, after discussing the subject in a general way, said that the pathogenic agents in purulent pleurisy are the staphylococcus, the streptococcus, the tubercle bacillus, and, in rare cases, the typhoid-fever bacillus, and that sero-purulent pleurisies are rarely associated with tuberculosis. In the treatment of pleurisy, the author rejects mercury and bloodletting, the former having never given him good results, while the latter increases the amount of the effusion. The salicylates, antipyrine, flying blisters, and poultices give some relief. Aspiration must be resorted to when the liquid reaches the level of the third rib.

Dr. Bozzolo, of Turin, then said that the typhoid-fever bacillus could be found in pleurisies oftener than is ordinarily believed. As to the treatment of purulent pleurisy, he very much prefers the operation of excision of part of a rib to simple aspiration.

Dr. Maragliano spoke of the association of pneumonia with pleurisy. He thinks that all cases of fibrinous pneumonia are accompanied by a pleuritic exudate between the third and fifth day of the disease. To be able to diagnose a small quantity of liquid in the pleural cavity, he places his patient in the genu-pectoral position. In order not to mistake the splenic dulness for that of effusion the patient is directed to lie upon the side opposite to that in which the effusion is thought to exist. In doing this the dulness of the spleen is displaced forward, while the pleuritic effusion moves toward the vertebral column. Among 216 cases of pleurisy he has observed 20 hæmorrhagic ones, only 7 occurring in tuberculous subjects, which shows that tuberculosis is not a *sine qua non* of hæmorrhagic effusion. Most of the hæmorrhagic cases were in alcoholics. In regard to treatment, he believes in an early aspiration, which he usually practises between the second and third week of the disease. Contrary to Dr. Maragliano, he thinks that purulent pleurisies should not always be evacuated by resection of a rib, spontaneous resorption being possible.

Dr. Bacelli, of Rome, said that by auscultation eight ounces of liquid can be demonstrated in the pleural cavity; that costal resections should not always be practised in cases of empyæma, and that a simple aspiration may be all that is needed. In cases of encapsulated purulent effusion, resection is indicated, but one must not forget that such operations are often followed by atrophy of the thoracic muscles.

Dr. de Renzi, of Naples, said that the etiology of pleurisy was variable, sometimes Fränkel's diplococcus being the cause, at other times a streptococcus, and, as an example, he mentioned the last epidemic of influenza, during which all pleurisies showed the presence of the streptococcus. He believes that tubercular pleurisy can be cured. Thoracic aspiration often immediately relieves the fever. The influence of pleurisy upon pulmonary tuberculosis may be either good or bad. It will have an unfavorable influence if the pleurisy appears on the healthy side, but if it develops on the same side as the pulmonary disease it may have a very favorable influence. This the author has observed in two cases in which all symptoms due to pulmonary tuberculosis disappeared after the evacuation of a pleuritic effusion.

Dr. Tomaselli, of Catane, recommended wet cupping at the beginning of acute pleurisy; he also employs blisters and the milk diet, aspiration being used only when the effusion persists too long.

Dr. Archangeli, of Rome, spoke of the success of surgical interference in purulent pleurisy, and said that Dr. Maneso, of Rome, has obtained 49 cures out of 52 operations.

Dr. Marino, of Messina, said that he had treated pleuritic exudates by compressed air, but the results were absolutely negative as regards increasing the rapidity of absorption of the exudate, and he thinks that aërotherapy should be reserved for the thoracic retraction consecutive to empyæma, especially in children and adolescents. Dr. Foazio, of Naples, thought aërotherapy very valuable in the treatment of pleuritic effusions.

Dr. Rovigli, of Modena, speaking on the subject of the displacement of pleuritic effusions by the change of position of the patient, said that among 40 patients which he examined for this purpose, only 14 presented a movable effusion, while in 12 of these the effusion was very slightly movable. He thinks that the instability of a

pleuritic exudate depends more upon the quantity than on the nature of the effusion.

Dr. Bianchi, of Florence, gave a short description of the clinical history of colloid cancer of the pylorus. He has found that this cancer is more frequent in men than in women; that it does not ulcerate very readily, and is not painful. Vomiting and dilatation of the stomach are absent, because the pyloric orifice remains open. As differential signs the author enumerated the following as belonging to this affection: When the patient lies on his right side liquid taken into the stomach rapidly passes into the intestine; again, when the patient is standing, if liquid is introduced into his stomach, it rises no higher than the level of the pyloric orifice, if one continues to introduce liquid, on account of the open pylorus. The only rational treatment is extirpation of the growth.

Dr. Filetti recommended a new way of staining fresh blood by means of dried methyl-blue, which colors the nucleus of the white corpuscles. Mr. Gualdi, of Rome, saw no advantage in this process over the one of Dr. Celli-Guarnieri, in which the methyl-blue is dissolved in ascitic fluid or serum.

Dr. Marchiafava, of Rome, spoke on the subject of pernicious intermittent fever, with symptoms of acute paralysis. This form of paralysis, he claims, is quite frequent, but is rarely fatal, as the lesions of the central nervous system are only secondary and dependent on a blood-stasis in the cerebral vessels.

Dr. Mya read a paper on the pathological value of the presence of urobilin in the urine. He has found that in patients suffering from pneumonia, acute rheumatism, typhoid fever, and anæmia, and in intoxication by antipyrine, pyridine, antifebrin, and other antipyretics, the quantity of urobilin is very great, which indicates a destruction of blood-corpuscles. In serious liver diseases we find only traces of urobilin, while in renal lesions urobilin is not found in the urine, but only in the blood.

Dr. Queirolo, of Genoa, spoke of the value of diaphoresis in the treatment of infectious febrile diseases. He said that in experiments undertaken by him 100 grammes of sweat from a healthy man produced no effect when injected in rabbits, while one-third less than that quantity of sweat obtained from patients suffering from typhoid fever, smallpox, etc., produced death. The latter result being obtained with sweat that had been sterilized, the infection cannot be due to a virus, but to a chemical substance, which, however, may be the product of pathogenic microbes. This fact encouraged the author to experiment on the elimination of poisons by the skin, and for this purpose he placed some of his patients in a sweating-room, with favorable results; the patient immediately felt better, and there was a remarkable change observed in the temperature, pulse, respiration, and nerve functions.

Dr. Farina, of Naples, in connection with this remarked that in Africa, where patients suffering from infectious diseases are subjected to sweating on account of the climate, diseases such as scarlet fever, typhoid fever, and measles terminate more rapidly than in Europe.

Dr. Masini, of Genoa, reported six cases of pulmonary tuberculosis treated by intratracheal injections of twenty-per-cent. solution of creasote in oil. Two patients were absolutely cured, although no bacilli had been found in their sputum; two were considerably improved, the fever disappeared, and the sputum and bacilli diminished in quantity, while in the two remaining the improvement was less marked.

Dr. de Lollis said, as a result of his observations on animals, that tannin is not incompatible with opium; and that an enema of opium and tannin will kill an animal as rapidly as an enema of opium alone.

NEW YORK.

To the Editor of THE MEDICAL NEWS,

SIR: It has been said that every new operation usually passes through three distinct stages before it takes its final position among the recognized resources of surgery: First, a period following its announcement, when it is enthusiastically praised; secondly, a stage of reaction, when all sorts of objections and adverse criticisms are heaped upon it, and when it is branded as nearly useless, if not in many cases actually harmful; thirdly, a stage of restitution, when reason again asserts itself, and, reinforced by the results of time and experience, places the operation in its true position before the profession. This description seems appropriate to many discoveries in medical science, and, perhaps, to none more than to Koch's great discovery of the tubercle bacillus. The many special systems of therapeutics which sprang up like mushrooms, almost before the scientific world had recovered from its surprise, have been but a "nine days' wonder," and we now hear fewer fascinating theories and more sober science. Dr. E. F. Brush, in a recent paper entitled "The Mimicry of Animal Tuberculosis in Vegetable Forms," has drawn some interesting lessons from the vegetable kingdom. Nut-galls are really tuberculous processes, affecting the breathing apparatus and nutritive channels of a plant. The gall-fly punctures the leaf and deposits an egg, injecting at the same time a minute drop of what has been called a poison, but which is, in all probability, a digestive ferment. This fluid gives rise to such changes in the nutritive process of the leaf that the irritation which the egg would otherwise cause is entirely overcome. This egg may be likened to the giant-cell of a tubercle in the human subject. An important lesson in therapeutics is to be found in a study of the pest known as the phylloxera, for this is a tuberculous disease due to a bacillus; yet, although its life-history is well understood, and the diseased parts are easy of access, treatment has been futile. It is not enough, therefore, to know that there is a germ constantly present in a mass of morbid material. But, if we have been disappointed in our therapeutic efforts to cure tuberculosis, our pathological studies are teaching us more and more how often Nature puts a stop to a tuberculous process which threatens to invade the whole system.

Dr. H. M. Biggs, not long ago, showed a specimen of tuberculosis of the pericardium. The two layers of the pericardium were adherent, and between them were several cheesy masses. The case was apparently one of primary tuberculosis of the pericardium, in which recovery had taken place, the tubercles having been surrounded by connective tissue, while the peritoneum had

subsequently become involved, and presented the usual lesions of tuberculosis. There were extensive adhesions binding down both lungs, but no tuberculous lesions were found here.

Aside from the unusual type of tuberculosis presented in this case, Dr. Biggs thought that it was of especial interest, as experience was gradually teaching him that there was apparently no form of tuberculosis which might not terminate in recovery. So, although gaseous enemata, heated air, and other similar "fads" have almost passed out of notice, Nature is constantly showing us how much she can accomplish in staying the hand of disease, if we will but assist her by maintaining good nutrition and providing the patient with proper hygienic surroundings.

The discussion at the Academy of Medicine the other evening on the subject of hydrophobia was something of a failure, if the object of those who arranged for it was to present a clear and authoritative statement of our present knowledge and beliefs concerning this disease, and of the plan of preventive treatment introduced by Pasteur; but the radical differences of opinion which were brought out, not only as to the efficacy of this special mode of treatment, but even as to the very existence of such a disease as hydrophobia, were ample justification for devoting an evening to the discussion. Incidentally, the newspapers and the Pasteur institutes came in for their share of adverse criticism, the former for the sensational accounts which they are continually publishing concerning the wonderful cures said to have followed the anti-rabic treatment, and the latter for their loose methods of investigation and of keeping the records from which their much-quoted statistics were compiled. In connection with this subject, it may not be amiss to note that in a very recent communication from Dr. Paul Gibier, Director of the Pasteur Institute of New York, he states that since it was opened on February 18, 1890, 610 persons who had been bitten by dogs or cats applied for treatment. In 130 of these the existence of hydrophobia in the animals was demonstrated, either by a veterinary examination or by inoculation experiments, and in many cases by the death of some persons or animals who had been bitten by dogs suspected of having rabies. All these persons were subjected to the anti-rabic treatment, and all remain in good health.

The annual meeting of the New York State Medical Association was held this Fall in its new home, the Mott Memorial Hall, 64 Madison Avenue. This building also contains the Association's library, which has grown very rapidly from a small beginning made in June, 1885, at the Carnegie laboratory. A little over five months later, the library contained 3448 books, and 4000 pamphlets. In December of last year it was decided to accept the offer of the trustees of the Mott Library to consolidate the two collections, and on May 5th of the present year the library was opened in its present location. There have been a number of large additions by bequests, and at present the library contains 8788 volumes, which with the 4000 volumes of the Mott collection, make a total of 12,788 books, besides about 5000 pamphlets. The library needs contributions of the recent medical, surgical, and obstetrical publications, a larger list of exchanges, and a permanent fund, which when invested will yield a sufficient sum to maintain and increase the number of books. The central location of this hall, and its quiet surroundings, make it a desirable retreat for the searcher into medical lore.

Progress in the direction of simplifying the practice of antiseptic surgery has been very rapid. Five or six years ago it was thought necessary to deluge the operating-field constantly with an antiseptic solution, and so zealously was this done, that some of our surgeons found it expedient to attire themselves in waterproof garments. Gradually the quantity of fluid employed was reduced, until now occasional sopping of the wound, or a final irrigation with bichloride solution, is considered sufficient. Antiseptic dressings are also less complicated, the Lister protective and the mackintosh being seldom used, while the eight layers of carbolized and resinous gauze have given place to soft bichloride "handkerchiefs," or to simple absorbent gauze, which has been previously steamed in a "sterilizer." Notwithstanding all this simplification, the list of bottles, dressings, dishes and other accessories necessary for the performance of any large operation according to modern ideas, is sufficiently formidable to make many a surgeon's assistant yearn for still greater simplicity. I recently saw a very convenient instrument-dish made of rubber, and capable of being inflated with air like an ordinary rubber ring bed-pan, or of being flattened out and packed away for transportation.

NEWS ITEMS.

Koch's Discovery.—Very little of interest has been developed during the past week concerning the discovery of Koch for the cure of tuberculosis. In this country a number of physicians have been fortunate enough to obtain some of the fluid for experimentation, Professor Chittenden and Dr. Foster, of New Haven, being the first to receive the fluid and to study its action by at least a week. They are now carrying out a series of experiments on three patients, one of whom is suffering from lupus, one from pulmonary phthisis, and one from laryngeal phthisis.

The Medical News during the past week sent a correspondent to New Haven for the purpose of discovering whether anything unusual had been noticed in the cases in that city after the injection of the fluid, but he was assured by the gentlemen who are using it that the symptoms noted were identical with those described in Koch's original paper, which was published in this journal.

Just as we go to press we hear that Dr. Jacobi and Dr. A. McLane Hamilton, of New York, have begun a series of studies with the liquid and that the committee of the University of Pennsylvania, consisting of Dr. Pepper, Dr. White, Dr. Musser, and Dr. Tyson, has done likewise.

Correspondence from Berlin, combined with newspaper dispatches, show that the possibility of a general distribution of the lymph for curative purposes, particularly in this country, will not be possible for several weeks. It is stated in one of the New York papers that the German Government will have the liquid for sale by the 15th of this month, but so far as we can learn, this is merely a newspaper report, based on very little authoritative information.

Several of the physicians who were in Europe at the time that Koch announced his discovery, have returned

to this country, after having gone to Berlin to investigate the value of the remedy. They all are in accord in stating that the hypodermic injections of the fluid act most favorably upon lupus, and they all insist that it is without value in pulmonary phthisis excepting in its earliest stages.

The latest reports of the cases of lupus under Levy and von Bergmann show that as time goes by the lesions are continually undergoing favorable changes, but these investigators very properly do not claim any permanent effects as yet, this being impossible in the case of a disease which is so slow in its formation as is lupus.

Dr. Dengel has published a paper in the *Berliner klinische Wochenschrift* which, while it endorses the opinions so far expressed, particularly emphasizes the harmfulness of the lymph in well-advanced cases of tubercular disease of the lung.

Much discussion has also been resorted to by the medical journals in Europe as to the composition of the liquid. Thus, Nencki and Sahli have published a paper in the *Correspondenzblatt für Schweizer Aerzte* upon "Enzymes in Therapeutics" with the idea of throwing some light upon Koch's remedy. They point out that the intravenous injection of these soluble ferments in various other diseases produces changes closely allied to those brought about by the liquid of Koch in tuberculosis. It is stated that the favorable action that follows the inoculation of the *streptococcus erysipelatus* into malignant tumors is probably due to the presence of the soluble ferment produced by the cocci. Again, the *Wiener medizinische Presse* publishes an article upon a similar subject, and argues that bio-chemical processes are involved in the production of the liquid, also pointing out that Sewall and others have proved that preventive inoculations with the poison of the rattlesnake finally render the organism capable of withstanding the poison. On the other hand, the *British Medical Journal* reminds its readers that, while these statements are of course very interesting, the possibility of heating Koch's liquid without destroying its specific action seems to render it unlikely that it has any such origin. The *British Medical Journal* also refers to a case, under the care of von Bergmann, in which the lupus disappeared under the use of the fluid, and was reported cured, but nevertheless recurred with great intensity a fortnight after the injections were stopped.

All the physicians who have returned so far from Berlin insist upon what THE MEDICAL NEWS has already insisted upon in previous issues, namely that it is exceedingly inadvisable for either doctors or patients to go to the German capital at the present time, owing to the number already striving unsuccessfully for opportunity to study or receive the liquid.

A number of the regular profession have been fearful ever since the publication of Koch's results lest charlatans should use some bogus liquid upon patients who are only too eager to be treated for consumption, and it seems that in Germany itself this fraud has been first attempted. It is stated that a janitor, named Meyer, who is employed in the Central Hotel, of Berlin, has been accused of selling to some foreign doctors 5 grammes of what he alleged was Koch's lymph, for 300 marks.

Cholera Rife in India.—Despatches from India to the New York *Herald* say that while the Second battalion of the Third Ghoorkha regiment was on the march in the Chin Hills several of the men were stricken with cholera. The troops went into camp at Guatheit, where thirty men, out of a total of sixty attacked, succumbed to the disease. The battalion subsequently broke camp and proceeded to Rangoon During the march many more soldiers were attacked by cholera.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM NOVEMBER 25 TO DECEMBER 8, 1890.

By direction of the Secretary of War, CHARLES B. EWING, *Captain and Assistant Surgeon*, in addition to his present duties, is assigned to duty as Examiner of Recruits at St. Louis, Mo.—Par. 7, *S. O. 275, Headquarters of the Army, A. G. O.*, November 24, 1890.

By direction of the Secretary of War, EUGENE L. SWIFT, *First Lieutenant and Assistant Surgeon*, is relieved from further duty and station at Fort McDowell, Arizona Territory, and assigned to Fort Thomas, Arizona Territory, where he is now on temporary duty.—Par. 16, *S. O. 282, A. G. O., Washington, D. C.*, December 3, 1890.

By direction of the Secretary of War, JAMES E. PILCHER, *Captain and Assistant Surgeon*, now on leave of absence, will report in person to the commanding general Division of the Atlantic, for temporary duty at Fort Columbus, New York Harbor, during the absence on leave of William E. Hopkins, Captain and Assistant Surgeon.—Par. 3, *S. O. 278, A. G. O., Washington, D. C.*, November 28, 1890.

By direction of the Secretary of War, leave of absence for six months, is granted WILLIAM E. HOPKINS, *Captain and Assistant Surgeon*.—Par. 2, *S. O. 278, A. G. O., Washington, D. C.*, November 28, 1890.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING DECEMBER 6, 1890.

ATLEE, L. W., *Assistant Surgeon*.—Ordered to examination preliminary to promotion.

MARTIN, H. M., *Surgeon*.—Placed on the Retired List, December 4, 1890.

ALFRED, A. R., *Assistant Surgeon*.—Ordered to the Naval Hospital, Norfolk, Va.

WHITFIELD, J. M., *Assistant Surgeon*.—Detached from the Hospital at Norfolk, and ordered to the U. S. S. "Chicago."

MCCORMICK, A. M. D., *Assistant Surgeon*.—Detached from the U. S. S. "Chicago," and wait orders.

KEENEY, J. F., *Assistant Surgeon*.—Ordered to the U. S. S. "Minnesota."

HARRIS, H. N. T., *Assistant Surgeon*.—Detached from the U. S. S. "Minnesota," and wait orders.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FROM NOVEMBER 24 TO DECEMBER 6, 1890.

FESSENDEN, C. S. D., *Surgeon*.—Leave of absence extended seven days, December 4, 1890.

BAILHACHE, P. H., *Surgeon*.—Granted leave of absence for twenty days, November 28, 1890.

HUTTON, W. H. H., *Surgeon*.—To proceed to Solomon's Island, Md., on special duty, November 29, 1890.

SAWTELLE, H. W., *Surgeon*.—Granted leave of absence for ten days, December 2, 1890.

PECKHAM, C. T., *Passed Assistant Surgeon*.—Granted leave of absence for ten days, December 1, 1890.

HUSSEY, S. H., *Assistant Surgeon*.—When relieved, to proceed to New Orleans, La., for duty, November 24, 1890.

GROENEVELT, J. F., *Assistant Surgeon*.—When relieved, to rejoin station, November 24, 1890.

COFER, L. E., *Assistant Surgeon*—Ordered to temporary duty at Boston, Mass., November 24, 1890.

SIR JOSEPH LISTER ON KOCH AND HIS METHODS.

SPECIAL CABLE DISPATCH TO THE MEDICAL NEWS.

KOCH AND HIS METHODS.[1]

AFTER some preliminary remarks about his journey to Berlin, Sir Joseph Lister said that the effects of Koch's treatment upon tubercular disease were simply astounding. As an example, he cited cases of extensive lupus of the cheek, in which two days after the injection the diseased surfaces became covered with crusts of dried serum, with no inflammation elsewhere. In cases of strumous glands in the neck the injections caused swelling of the glands with redness of the skin over them and pain. In gelatinous disease of the knee-joint similar effects are observed, only the tubercular tissue being affected.

The systemic effects which follow the injections are severe for a few hours, and consist in transient fever, pains in the limbs, shivering, nausea, and sometimes vomiting. The usual dose of the lymph is one-thousandth of a gramme diluted with water to one gramme. The method is useful in the diagnosis of suspected latent tuberculosis. The therapeutic effects on lupus are separation of the crusts, leaving a more or less sound scar. In tubercular joints the swelling diminishes. In phthisis the sputa becomes scantier and more mucous, the bacilli diminish in number, the sweats disappear, the patient gains in weight, and the physical signs of pulmonary tuberculosis vanish. The important questions are, How far are the effects permanent, and What are the limits to the curative power? Diseased tissue is expelled by sloughing or is absorbed; spontaneous expulsion of deep-seated caseous masses being impossible, fresh infections would demand further and indefinitely prolonged treatment for the production of immunity from tubercular infection.

If it is true that the living but diseased tissues surrounding the tuberculous masses are acted on by the remedy, and are rendered capable of resisting the development of bacilli, then caseous masses would remain harmless as regards further infection, and tubercular disease would be definitely cured, for immunity is wanted to make the treatment perfect. Immunity has been attained in guinea-pigs by very large doses, and perhaps could be attained in man by gradually increasing the size of the doses. Acquired tolerance is best shown by the greatly increased dose borne after several injections. It would seem probable that by steadily pushing the dose a degree of tolerance might be attained equal to immunity.

Sir Joseph Lister then continued as follows:

There is another line of inquiry from which I cannot help hoping for good results. Through Koch's great kindness I had the opportunity of penetrating into the arcana of the Hygienic Institute of Berlin, where I saw most beautiful researches carried on in that institution, of which Koch is the inspiring genius. I saw things which, while they excited my admiration, made me also feel ashamed that we, in England, from one circumstance or another, are so greatly behind our German brethren.

[1] Abstract of an address published in the London Lancet of December 13, 1890.

The researches to which I desire especially to refer are still in progress, and fresh facts are accumulating day by day though they have not yet been published. I am not at liberty to mention details, but there can be no harm in my saying this much, that I saw in the case of two of the most virulent infective diseases to which man is liable, the course of the otherwise deadly disease cut short in the animals on which the experiments were performed, by the injection of a small quantity of a material perfectly constant in character, an inorganic chemical substance, as easily obtained as any article in the materia medica. Not only this, but by means of the same substance these animals were rendered incapable of taking the disease, and under the most potent inoculations perfect immunity was conferred upon them.

I suspect that before many weeks have passed the world will be startled by the disclosure of these facts if they can be applied to man, although our experience of the different behavior of Koch's fluid in guinea-pigs and in the human subject makes this a matter of uncertainty until tested by experiment. But if they can be applied to man, the world will be astonished, and the beneficence of these researches will be recognized everywhere.

At the present time Koch is engaged in the earnest endeavor to produce his remedy for tubercle by some process which could be divulged without the risk of the public being supplied either with material useless from its inertness, or. on the other hand, a deadly poison. Koch, I believe, would not have published his method had it not been for the great pressure brought to bear upon him, until he could produce it in a form capable of being revealed in every detail.

It is nothing but the fear that by publishing now the specific mode of preparing this material he might do immense harm instead of good that prevents him from making it known, and I must say that the carping criticism against Koch, on account of what is spoken of as a "secret remedy," can only proceed from absolute ignorance of the beautiful character of the man. If it should happen that, as with the other diseases to which I have referred, so with tubercle, complete immunity should be obtained by means of some inorganic chemical substance which anyone can prepare, then would be achieved the complete triumph of the treatment of tuberculosis; and, for my part, I rejoice that we are permitted to look forward with hope to that glorious consummation.

AMERICAN REPORTS ON KOCH'S METHOD OF TREATING TUBERCULOSIS.

The following reports have been received from physicians in New York, Baltimore, and Philadelphia, and are of interest, not only because of the importance of the subject, but also for the reason that they are the first authentic publications of American experience:

REPORT OF CASES TREATED BY KOCH'S LYMPH.

By DR. FRANCIS P. KINNICUTT, M.D.,
PHYSICIAN TO ST. LUKE'S HOSPITAL, NEW YORK.

Up to the present date fifteen patients suffering from various forms of tubercular disease have been inoculated by me with Koch's lymph, in the wards of St. Luke's Hospital.

The cases were carefully selected with the view to study thoroughly this method of treatment. All of them will remain under my personal observation in the hospital during the entire period of treatment, and a detailed report of their histories, subsequent to inoculation, will be published from time to time.

The cases are as follows: Two cases of lupus of the face; one case of lupus of the hand, accompanied by tuberculous infiltration of a limited portion of one lung; two cases of tuberculous glands (cervical); three cases of hip-joint disease, with intermittently-discharging sinuses; one case of tuberculous disease of the tibia and fibula, with open sinus; one case of prostatic surface tubercular disease; four cases of pulmonary tuberculosis in its early stage and limited in area; one case of doubtful diagnosis is embraced in the above group.

Thus far 0.001 gramme of the lymph has been used for the initial inoculations in all adult cases, and 0.005 in children. Decided reactions have been obtained in all patients but one of the fifteen inoculated. The reactions have been varied in the time of their appearance—from four hours after inoculation to twenty four; also in their intensity and duration. The longest duration of the reaction has been forty-six hours. The highest temperature recorded during the reaction has been 104° F. The increase in the pulse-and respiration-rate has been proportionate to the rise in temperature. The local changes in the cases of lupus have corresponded very exactly with those recorded by the Berlin observers, and have been of the greatest interest. The differential diagnosis in the doubtful case mentioned lay between lupus of the throat and a tertiary specific lesion. No reaction followed the inoculation of 0.001 gramme, and a second of 0.002 gramme, and the case was accordingly regarded as one of specific disease. No symptoms which could occasion any apprehension have been observed in any of the cases. Tables are appended showing the symptoms and signs observed during and following inoculations in three patients presenting different forms of tubercular disease. The local changes observed in the

case of lupus are kindly described by Dr. George H. Fox, by whom the patient was sent to me.

The diagnosis of tubercular disease of the prostate in Case II. was made by Dr. Keyes, by whom the patient was referred to me. The reaction obtained would seem to be corroborative of this diagnosis.

At the present moment, in the stress of increased time and labor demanded by the treatment and observation of the large number of new cases admitted to the wards of the hospital, only the above brief notes are possible.

Notes on Case III. *Lupus vulgaris of left ear.*—On December 11th, at 3 P.M. (date of first injection of lymph), the case presented the following appearance:

The left auricle was considerably thickened, of a dull-red hue and partly covered by adherent flakes of dead epidermis. Below the ear was a rounded, circumscribed patch of lupus, about the size of a silver dollar, the smooth surface of which presented well-marked cicatricial lines, the result of previous scarification. This patch extended for a short distance up behind the ear. Between the paler lines the dull-red hue of the lupoid tissue was still apparent. During the patient's two weeks' residence in St. Luke's Hospital there had been no sensation of pain, burning, or itching in the affected part.

On December 12th, at 3 P.M., there was so marked a change in the appearance of the ear that it was noticeable at first glance, even at a distance. The affected part appeared as though it were acutely inflamed or erysipelatous. The auricle had assumed a bright-red hue, and was considerably swollen. The patch beneath and behind the ear was notably elevated, and the redness had increased to such an extent that the cicatricial appearance of the surface was no longer apparent. At the margin of the patch there was a narrow zone of hyperæmia and a number of prominent red points which had not been noted on the preceding day, and which doubtless indicated the most recent infiltration of the healthy tissue. The patient stated that a burning sensation had occurred during the previous night, and the ear had felt quite painful toward morning. It now felt as it looked, swollen and inflamed.

On December 13th the elevation of the patch and swelling of the auricle had subsided, and the color was less inflammatory. The burning sensation had gone. The epidermic flakes, especially upon the helix of the ear, were dry and whitish. At a single point on the patch below the ear a serous exudation was noted. A second injection of lymph was made.

On December 14th there was not much change in the affected part. There was a slight increase of inflammation, but by no means so marked as after the first injection, although double the dose had been employed.

There was no elevation of the margin of the patch, and the lobe of the ear felt a trifle softer. Below and behind the ear there was a slight moist discharge, with a tendency to honey-like crusting. The patient stated that during the previous night she experienced "a heavy, stupid, sick feeling," and felt a sharp pain in the ear as after the first injection, but the sensation of burning and swelling was much less this time.

On December 15th it was simply noted that the surface of the affected part presented more of an eczematous appearance.

Case I. *Tubercular infiltration of apex of right lung.*—Female, aged forty years. Sputa contain very numerous tubercle bacilli. No rise of morning or evening temperature during two weeks previous to inoculation. General condition good.

First inoculation, December 10th, 11 A.M., 0.001 gramme. Reaction developed five hours after inoculation; slight chilliness, headache, general malaise, fever. Duration of reaction twenty-one hours. Highest temperature 101.2°. Amount of sputum for twenty-four hours preceding inoculation, 11 drachms; for twenty-four hours following inoculation, 13 drachms; for second twenty-four hours following inoculation, 18 drachms; for third twenty-four hours following inoculation, 3 ounces. Urinary examination: a trace of albumin present both before and after inoculation. Physical signs consisted in crepitation over affected area more marked, with mucous râles in larger tubes of same; no enlargement of spleen.

Second inoculation, December 13th, 3 P.M., 0.001 gramme. Reaction developed thirteen hours after inoculation. Duration of reaction nineteen hours. Highest temperature 101.2°, seven hours after beginning of reaction. Amount of sputa for twenty-four hours following inoculation, 3 ounces. Urinary examination: trace of albumin, otherwise negative. Physical signs: bronchial element of respiratory murmur distinctly more marked, and physical signs of infiltration obtained over an increased area; no enlargement of spleen.

Third inoculation, December 16th, 3 P.M., 0.001 gramme.

Case II. *Prostatic surface tubercular disease.*—First inoculation, December 11th, 3.30 P.M., 0.001 gramme. Temperature normal. Reaction developed seven and a half hours later; rigors, headache, pains in limbs, general malaise, fever. Duration of reaction thirty-one hours. Highest temperature 104°. Local symptoms, pain and uneasiness over region of bladder, increased irritability of same. Urinary examination: small amount of albumin present before inoculation; distinctly increased during reaction.

Second inoculation, December 13th, 3.30 P.M., 0.001 gramme. Reaction developed four hours later. Duration of reaction thirty hours. Highest temperature 101⅘°. Local symptoms similar to

those following first inoculation. Urinary examination same as preceding, with a few hyaline casts.

Third inoculation, December 16th, 3 30 P.M., 0.001 gramme.

Case III. — Female, aged twenty-two years. *Lupus of ear and contiguous portions of face and neck, of twelve years' duration.* Under treatment for the greater portion of this time.

First inoculation, December 11th, 3 P.M., 0.001 gramme. Temperature normal. Reaction developed nine hours later; slight rise of temperature and burning sensation in affected ear. Duration of reaction twenty-one hours. Highest temperature 99.8°. (Local signs described in appended note.) Urinary examination negative. No enlargement of spleen.

Second inoculation, December 13th, 0.002 gramme. Reaction developed eleven hours later; slight fever, decided burning sensation in affected ear. Duration of reaction twenty-two hours. Highest temperature 100.6°. Local signs described elsewhere. Urinary examination: trace of albumin, otherwise negative. Physical signs negative; no enlargement of spleen.

Third inoculation, December 16th, 0.003 gramme.

PRELIMINARY REPORT ON KOCH'S LYMPH.

By WILLIAM OSLER, M.D.,

Professor of the Principles and Practice of Medicine in the Johns Hopkins Hospital.

At the meeting of the Johns Hopkins Hospital Medical Society, December 15th, Dr. Osler made a preliminary report on the cases—eleven in number—under treatment by Koch's method. He said: "In the presence of an alleged discovery of such importance we should neither display a blind credulity nor an unreasonable scepticism. The extraordinary enthusiasm which has been aroused in the profession by the announcement is a just tribute to the character of Robert Koch, who is a model worker of unequalled thoroughness, and whose ways and methods have always been those of the patient investigator, well worthy of the unbounded confidence which every expert in pathology places in his statements. The cold test of time can alone determine how far the claims which he has now advanced will be justified, and meanwhile the solution of the question—so far as human medicine is concerned—has been transferred from the laboratory to the hospital wards, in which the careful observations of the next few months should give the necessary data for final judgment.

"In the selection of cases of pulmonary tuberculosis we have begun with patients not far advanced in the disease, and with little or no fever—cases, too, which we have had under observation for some time, and in whose sputa bacilli and elastic tissue have been repeatedly found. We began on Friday, December 12th, the day on which we received the lymph, through the kindness of Dr. Billings, to whom, as stated in a communication from Professor Koch, the first sample of the fluid was sent in America. One-tenth of a cubic centimetre of a one-per-cent. solution was used for the first injection, and as no reaction followed 0.2 c.cm., and then 0.5 c.cm. were used. With the latter strengths the reaction has, in each instance, been fairly characteristic. Hourly observations have been made in each instance, and there has been within six or eight hours a rise in temperature of three or four degrees. In one case there was a slight chill. The constitutional disturbance has not been great, and the chief complaints have been of restlessness, sleeplessness, and slight pains in the back and limbs. In three cases the cough was greatly aggravated. So far, no change of note has been observed in the sputa. The physical signs will be recorded only once in each week, as it is believed that any changes can be better appreciated after these intervals. Two cases of pleurisy—one chronic and one acute—have received injections for purposes of diagnosis. The chronic case was suspected to be tuberculous, but there are no signs of affection of the lung and no expectoration. He is showing reaction after the third injection. The acute case, as yet, has no special symptoms. No advanced cases have been treated, nor is it thought that much can be expected from the method after large cavities have formed and when numerous foci of softened tissue exist in the lungs. No unpleasant effects have, as yet, followed the injections."

Several of the male patients were shown to the Society, and the charts of the hourly observations passed around for the inspection of its members.

[*For conclusion of the reports see page 670.*

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LVII. SATURDAY, DECEMBER 20, 1890. No. 25.

ORIGINAL LECTURES.

ON THE FORM OF CONVULSIVE TIC ASSOCIATED WITH COPROLALIA, ETC.

Clinical remarks made to the Post-graduate Class in Medicine, Johns Hopkins Hospital, Baltimore, October 11, 1890.

BY WILLIAM OSLER, M.D.,
PROFESSOR OF THE PRINCIPLES AND PRACTICE OF MEDICINE, JOHNS HOPKINS UNIVERSITY.

GENTLEMEN: There is a curious disease—or perhaps, more correctly, symptom-group—met with chiefly in children, to which attention has been called of late by French writers, which is characterized by irregular, spasmodic movements, the utterance of involuntary explosive sounds or words, and mental defects of various sorts. It is not a very common affection in this country, and I take this opportunity to bring to your notice a case which we have been studying for the past few weeks.

The cases have usually been described as chorea, or "habit-spasm," both of which conditions are simulated very closely by the irregular movements; certain instances also have been reported as hysteria.

Unfortunately Charcot and his pupils, Guinon and Gilles de la Tourette, have given to this affection the name *maladie des tics convulsifs*. I say unfortunately, for here and in England we use the term *convulsive tic* to characterize a totally different affection, involving usually the facial muscles and of either central or peripheral origin, but not necessarily coming on in childhood and not characterized by the other features presented by the disease of which we are at present speaking; and thus it happens that if we turn to the recent editions of French books we find under *tic convulsif* a disease very different from that described by the same name in English and American works.

The history of our patient is briefly as follows:

Mary ——, aged thirteen years, applied at the out-patient department, July 10th, and was under observation there until September 16th, when she was admitted to ward G. Her mother brought her to the hospital on account of irregular involuntary movements and curious barking-sounds.

Her family history is good. Her mother is a bright, intelligent woman, a German by birth, and has had ten children, none of whom have been affected as is this girl—the third child. There is no tendency to mental disease in the family. The birth of the child was normal and there is no history of convulsions in infancy. She has had scarlet fever, but has not had rheumatism.

Since her fifth year she has been subject to involuntary jerking movements of the arms and head, which vary very much in intensity, sometimes better, sometimes worse, and they have usually been called by the doctors chorea. They have not interfered with her development or her education. She has not yet menstruated For the past year she has been making curious sounds; beginning by saying "hah" very frequently. Sometimes she would bark like a dog. She would also call out the names of people, and if she heard a new name she would be apt to repeat it.

Her condition on admission was as follows: A bright, intelligent child; well educated, writes nicely, takes an interest in her books and has evidently been ambitious at school. She is nervous, the right arm occasionally twitches and the head jerks. There are no grimaces, but on several occasions she seemed to mimic movements of the face. Every now and then she calls out "hah," "Bridget," or "stools," or says in sharp, clear tones "bow, wow." There are no disturbances of sensation, and the special senses are unimpaired. Examination of the heart and lungs was negative; the thyroid gland is slightly enlarged.

Throughout the latter part of July and in August attempts were made to treat the case by hypnotic suggestions, at first with success, but subsequently without any improvement.

On September 8th her mother wrote the following letter, which illustrated a new phase of the child's malady:

"Mary makes use of words lately that make me ashamed to bring her to you or take her out of the house; it is dreadful, such words as ——, ——, ——, etc. She was always a modest child, and it almost kills me for to hear her use such words."

Her mother was asked to bring her again and was told that this was really a part of the affection, and, like the movements, involuntary in character. The child seemed more depressed, had lost flesh and, her mother said, had changed mentally. She was very obstinate, and almost invariably did what she was told not to do, and had threatened to take poison. She will say the bad words aloud or mutter them to herself.

On admission to the hospital she was placed in a room by herself, kept in bed, and encouraged in every way to cease making the sounds and to stop the use of the bad words. During the first two weeks she improved very much. The movements were reduced in frequency and sometimes during my visit they would not be noticed at all. They most commonly affected the right arm, which, with the hand, was drawn up in a sudden electric-like jerk. The head and neck would jerk simultaneously or alone. Sometimes there was combined movement of the neck and chest-muscles. The involuntary expressions of which she made use were those mentioned above; a sharp bark was the most frequent sound, which, from its ringing quality, could be heard at a considerable distance.

She was so much better that she was allowed to get up and another patient was placed in the room with her. This seemed to excite and worry her, and shortly afterward the barking sounds became much more frequent,

occurring every one or two minutes, and she complained of great soreness of the muscles of the chest and abdomen. The movements, however, did not increase. She was again placed in seclusion and in bed, and again improvement followed, but she still barks and she has not given up entirely the use of bad words.

She is a docile, intelligent child, and seems anxious to get well. She has kept a diary, which displays no special peculiarity. She writes verses, which are not worse than those usually composed by girls of her age.

The patient, as you see, is a bright, intelligent child, and there are still to be seen occasional lateral jerkings of the head, and now and then the right arm is elevated with great quickness. You have also heard the peculiar sharp sound which she makes from time to time, which sometimes resembles a hiccough. More commonly it has a barking quality, which is not nearly so marked as it was some weeks ago, when usually two of the sounds succeeded each other with rapidity. In addition, this child has presented several of the symptoms which Charcot and his pupils regard as characteristic of the affection.

I have just spoken of the emission of involuntary sounds and words. The use of bad words, for which the ingenious expression *coprolalia* (fæcal speech) has been invented, is present in very many of the cases, forming a feature very distressing to the relatives.

You can judge from the letter of this child's mother how grievously troubled she was over our patient's "slips of the tongue." She cried bitterly when she told us of it, and said that she wished her daughter would die. In some of the reported cases, even children of five or six years have persistently used words of the most obscene character.

A second peculiarity of a similar nature is the repetition of any sound or word heard, for which the name *echolalia* is employed by Charcot. It is a veritable echo, and the word is repeated by the patient so soon as heard. In our case this did not often occur, but, on hearing a new name, she would be apt in a short time to repeat it very often; thus, on first coming into the hospital, she used for some time the word "nurse," which she was constantly hearing.

The facial mimicry was noticed on several occasions, but has not been a special feature. This curious imitation of muscular movement has been described, not only in the face muscles, but in those of the extremities, and simulates closely those of the remarkable Malay disease known as *latah*. The term *echokinesia* has been applied to this mimicry of movements.

So far, our patient has not presented any symptom of mental disorder, unless indeed her extreme obstinacy and her addiction to poetry could be so considered. Upon this aspect of the affection Charcot lays great stress, and thinks that sooner or later the cases invariably show psychical changes. By far the most common mental change is the existence of fixed ideas, and Guinon, whose article in the *Dictionnaire Encyclopédique* is the most extensive on the subject, describes these as very often a fear of impending trouble, or a fear of places (*agoraphobia*). In other instances there is "*folie pourquoi*," in which the patient incessantly demands the reason for the performance of even the simplest actions of life.

"*Folie du doute*" and the curious, irresistible impulse to touch certain objects, may also be present. Another form of this obsession which has been noted in some instances, is what has been termed *arithmomania*, in which the patient is possessed with an irresistible desire to do some special mathematical problem, or to count up to a certain number before doing a certain action.

In brief, the main peculiarities of the disease are: the involuntary movements, the uttering of words or cries, coprolalia, mimicry of words or movements, and, in very many instances, mental symptoms, chiefly some form of obsession. The majority of the cases present only the first two or three of these features, and it is not until the more advanced stages that the mental symptoms become marked.

The prognosis, according to Charcot and his pupils, is extremely grave, and very few cases recover, but years may elapse before the onset of mental symptoms. The diagnosis is easily made in cases such as the one before you; but there are several conditions which in certain features simulate the disease very closely. Thus coprolalia and the irresistible tendency, on all occasions, even the most solemn, to use obscene words have been described apart from any motor phenomena. There is the oft-quoted case of the Marquis of Dampierre, who, from early youth to his ninetieth year, involuntarily uttered, even under circumstances the most solemn, the words "*merde!*" and "*foutu cochon!*"

Still more common is the existence, particularly in children and youth, of a fixed idea. One of the commonest is the "*dilirie de toucher*," which impels the individual to touch certain objects, and of which the great Dr. Johnson, as is well known, was a subject. One of the most graphic accounts, probably autobiographical, of this imperative impulse to touch objects is given by George Borrow in his *Lavengro, the Scholar, the Gypsy, and Priest*, in which the practice was followed in order to prevent evil happening to the lad's mother.

In many points the affection has a close resemblance to the common habit-chorea or habit-spasm, with which indeed the involuntary movement of convulsive tic is identical. I do not remember, however, to have seen at the Philadelphia Infirmary for Nervous Diseases, among the numerous cases of habit-spasm which came to our clinics, particularly to the clinic of Dr. S. Weir Mitchell, a single instance in which other symptoms developed.

I had one case with facial spasm, in which the lad put his middle finger into his mouth and bit it severely, and at the same time with the index-finger compressed the tip of his nose. This habit had continued for a long time, and had resulted in the production of a thick callosity on both surfaces of the second phalanx of his finger. A somewhat similar trick is reported to have been practised by Hartley Coleridge when a boy, only, if I recollect aright, he was in the habit of biting his arm. And quite recently there was at the clinic a girl nine years old, who, during convalescence from chorea, developed the curious trick of first smelling and then blowing upon anything she took into her hand.

With hysteria the relations of the disease are not thought to be very close by Charcot and his pupils. The affection usually sets in at a period of life earlier than that at which hysterical symptoms begin, and very many of the cases show no manifestations of hysteria

The utterance of loud involuntary cries and anomalous sounds is, however, a special feature of certain cases of hysteria which may thus present a resemblance to this form of convulsive tic. They, however, are not necessarily associated with involuntary movements, and are usually of a more bizarre character. I remember a remarkable case of the kind which was brought into Professor Wagner's clinic at Leipsic. A child, aged about fourteen years, had for several weeks uttered the most remarkable inspiratory cry, followed by a deep-toned expiration, both of which were audible at a great distance. They persisted during the day with each respiration, but ceased during sleep. The child was worn to a skeleton.

Dr. Gapen, of Omaha, brought to the hospital last year a phonographic cylinder, on which was recorded a most remarkable hysterical cry which the patient, a young girl, had been in the habit of uttering for many months, and which was loud enough to be heard at a distance of several blocks. These cases, however, usually present other features which make the diagnosis clear.

As was the case in this patient, the affection begins at an early period, in a majority of the cases, according to Guinon, from the sixth to the twelfth year. They are commonly regarded as chorea.

An hereditary neuropathic taint has been present in many instances.

We have treated this child in the hospital by seclusion and rest in bed, and have made moral rather than physical efforts to improve her condition. She is certainly better, particularly in the matter of the use of bad words.

THE TREATMENT OF PNEUMONIA.[1]

BY J. C. WILSON, M.D.,

PHYSICIAN TO THE HOSPITAL OF THE JEFFERSON MEDICAL COLLEGE, AND TO THE GERMAN HOSPITAL, PHILADELPHIA.

THE subject of the treatment of pneumonia is trite and well worn, I admit; but its earnest consideration enters into the everyday life of all of us. Those among us whose views as to the proper treatment of this familiar disease are definitely settled are few, and friendly interchange of opinion upon the subject is likely to be useful. What I shall have to say relates solely to croupous pneumonia, and has no special bearing upon so-called catarrhal pneumonia, broncho-pneumonia, or any form of secondary pneumonia whatever.

Croupous pneumonia occurs with great frequency in connection with other diseases. It is not uncommon during convalescence from acute infectious processes. Those who suffer from chronic Bright's disease and from valvular and degenerative diseases of the heart and from organic diseases of the nervous system are especially prone to it. It not unfrequently occurs as the terminal condition in these affections and in other constitutional diseases, such as diabetes mellitus and pulmonary phthisis. Under these circumstances, it preserves, however, its own clinical and anatomical characters, and must be regarded, not as a mere complication of preëxisting pathological processes, to which it has no essential causal relation, but as an entirely independent intercurrent disease.

When we consider the modifications of pneumonia under these circumstances and in the different periods of life from childhood to old age, and in alcoholic subjects, we are impressed with the uselessness of attempts to show by statistics the value of different plans of treating the disease. No general percentages of mortality can be relied upon as indicating the efficacy of a treatment, unless they are on a large scale and in connection with a critical analysis of the condition of the patients. It is a question of the seed, which is probably always the same, and the soil, which is infinitely modified. The only reliable test of the value of treatment is its effect upon the general course of the disease, a test which is much influenced by the personal equation of the observer. For this reason plans of treatment once in vogue, credited with surprising results in reducing the mortality of the disease, have failed to stand the test of time and have passed into disuse. And while the profession unites in striving after some specific treatment for other infectious diseases, the present drift of opinion in regard to croupous pneumonia seems by common consent to be in the direction of a vigilant expectancy with active treatment of symptoms as they arise.

Whether we regard acute lobar pneumonia as a specific inflammation, or, in the language of the day, as an acute infectious febrile disease, of which the pulmonary lesions are merely a localization, we recognize in its causation three factors—a pathogenic bacterium, a predisposition, and an exciting cause—in other words, the seed, the soil, and the implantation. Nothing in the process is more obvious than its specific nature. Against this neither the existing uncertainty as to the actual bacterium which causes it, nor the fact that the local lesions sometimes terminate in gangrene or in abscess, militates in the slightest degree.

Pneumonia cannot be regarded as a simple inflammation. This being the case, the antiphlogistic treatment of former times scarcely deserves discussion. Indiscriminate bloodletting as a routine treatment for a specific pathological process, the natural history of which shows it to be self-limited and of comparatively short duration, is not in accordance with modern therapeutic principles. Still less are repeated venesections and bleeding *ad deliquium*. Patients recovering after such treatment

[1] Read before the Alumni Association of Jefferson Medical College, November 25, 1890.

do so, not as a result of it, but despite it. In connection with this, one turns with interest to the words of Trousseau: "The necessity, the utility, even, of bleeding does not appear to me to have been made out so clearly as is believed by the majority of physicians, to whom the denial of the efficacy of extracting blood in pneumonia would seem the denial of a demonstration." The investigations of Magendie, Dietl, Niemeyer, and others into the natural history of croupous pneumonia had already called attention to the uselessness and dangers of indiscriminate bleeding. In recent years attempts have been made to show that the disuse of bloodletting in pneumonia has resulted in a notable increase of the death-rate as made manifest by a comparison of recent with older statistics. The unreliability of mortality statistics in pneumonia has already been alluded to. The special error in the statistics of this disease arises from the fact that prior to the middle of the present century the diagnosis of croupous pneumonia was by no means an exact one, and many other pathological processes affecting the chest were very commonly set down as pneumonia. Furthermore, Townsend and Coolidge have shown from a critical analysis of a thousand cases, treated in the Massachusetts General Hospital, from 1822 to 1889, that the increase in the death-rate is misleading for other reasons. The average mortality was twenty-five per cent. This gradually increased from ten per cent. in the first decade to twenty-eight per cent. at the present time. But the average age of the patients has been increasing from the first to the last decade. The relative number of delicate and complicated cases has also been increased, as has the relative number of foreigners. These authors do not regard the treatment, which was heroic before 1850, transitional between 1850 and 1860, and expectant and sustaining since the last date, as having influenced the mortality-rate, the duration of the disease, or its convalescence.

We all recognize the occasional necessity for venesection in the early stages of croupous pneumonia. It often gives relief from urgent dyspnœa and pain, and sometimes even appears to save life. It cannot, however, be considered as a specific treatment. It must be regarded as symptomatic, like wet cups and leeches, which likewise give relief under similar circumstances in a way that is not understood. In the same manner we condemn the treatment by tartar emetic in large doses, and with it is to be relegated to the limbo of discarded medicaments in pneumonia Trousseau's lauded *kermès*. The treatment by large doses of veratrum viride in the early stages, which still survives and finds in many quarters earnest advocates, is based upon the same antiphlogistic idea and has little to commend it. To add the depressing effect of a powerful drug to the pathological influences already depressing the heart is now recognized as increasing the danger of cardiac failure. In fact, if, as our knowledge of croupous pneumonia indicates, many of the symptoms are due to a toxæmia, it were better to bleed the patient, if he is to be bled at all, into a basin than into his own vessels. To depress the heart by veratrum viride or aconite in the first stage, and to harass it by digitalis at a later period are among the vagaries of a therapeutics which takes pleasure in vaunting itself as rational. To give cardiac depressants in croupous pneumonia is always of doubtful expediency, and digitalis as a cardiac stimulant should be administered only in response to special indications. Of the latter drug Brunton says, "It is of little use in pneumonia."

Efforts to discover a specific, *i. e.*, an antiseptic or germicide treatment for croupous pneumonia have not been followed by success. The most recent attempt in this direction is the suggestion of Bartholow in regard to the use of ethyl iodide by inhalation. The anæsthetic and antispasmodic properties of this drug may render it, when cautiously used, a valuable addition to our resources in the management of pneumonia, but its antiseptic and germicide properties are feeble, and there is no experimental evidence to show that it has, in the high dilution in which it reaches the residual air, any effect upon any of the forms of bacteria present in the pneumonic exudate. Furthermore, there is reason to believe that the pathogenic bacterium has already done its work so far as the lung is concerned when the exudation as manifested by dulness and bronchial respiration is established.

It remains to speak of the treatment of pneumonia by systematic repeated cold or tepid bathing, as practised by Jürgensen at Kiel and Tübingen. Notwithstanding the fact that this treatment, as shown by certain series of statistics, has resulted in an apparent reduction of the mortality amounting to fifty per cent., it has never come into general use, either in Germany or elsewhere. A partial explanation for this undoubtedly lies in the fact that a large proportion of the cases recover under ordinary methods of treatment, and, further, the application of every bath is a disturbance to the patient, which is at least troublesome. Finally, in the absence of conclusive evidence of the efficacy of bathing as a plan, it is impossible to overcome the traditional objections to it on the part of the people.

As yet, we know no remedy of which it can be positively said that it is capable of controlling or aborting the pneumonic process. In affirming this I do not overlook the fact that large doses of quinine given early in the disease are thought by many to exert a favorable influence upon the subsequent course of the attack.

The milder cases run a favorable course and get well without the use of perturbating remedies. The treatment must, therefore, in the present state of knowledge, be expectant. But this expectancy is not idle; it it alert and vigilant, and abundant in resources. It is expectant-symptomatic.

I will speak briefly of the hygiene of the sick-room. The room itself should be large and well lighted, but so arranged that the lighting can be controlled to suit the sensations of the patient. It should be well ventilated, care being taken that the patient is not exposed to draughts. The ideal room for the treatment of pneumonia, or, in fact, almost any of the acute infectious diseases, is like that described in the newspapers as occupied by the Iron Chancellor—large, airy, and well lighted, without furniture, except a military bedstead, a small table, and a chair for the attendant. The patient is not liable to take cold, and requires, above, all an abundance of fresh air. The bed-clothing should be light, but occasionally varied in accordance with the sensations of the patient. The food should be of the simplest and most digestible kind, and during the earlier stages administered sparingly.

A laxative dose of calomel, from three to five grains, at the beginning is useful. It may require repetition later.

The prominent symptoms after the initial chill are the fever, with or without delirium, the pain in the side, the difficulty and distress in breathing, and the cough. The chief danger lies on the side of the circulation, the cause of death in the majority of fatal cases being heart-failure.

The most striking peculiarities of the fever of pneumonia are the suddenness of the rise and its extent; but the importance of the high temperature of pneumonia has been overrated. Welch, in his *Cartwright Lectures*, 1888, carefully analyzes the experimental and clinical data bearing upon this subject. He shows that animals may be kept at a high temperature for at least three weeks without manifesting serious symptoms. The functional disturbances to be attributed directly to the influence of elevated temperature are increased frequency of the respiration and quickened pulse. No definite relation can be established between the variations of arterial tension which occur in fever and the height of the temperature. Though prolonged high temperature is an element in the causation of fatty degeneration of the heart, there are other factors, such as infection, concerned in the production of the lesion. The lessened perspiration, the renal disorders, and the digestive disturbances, with the possible exception of constipation, are always referable chiefly to other causes than the increased temperature. Both experimental and clinical observations strongly support the view now widely accepted that the disturbances of the sensorium, which constitute so prominent a part in the group of so-called typhoid symptoms, are dependent in a far greater degree upon infection or intoxication than upon the heightened temperature. In support of the conclusions derived from the experimental study of the effect of heat upon men and animals, Dr. Welch called attention to the absence of all serious symptoms in many cases of relapsing fever, and in the so-called aseptic fever, in spite of prolonged high temperature. In conclusion he emphasized the fact that those fevers, such as typhoid fever and pneumonia, in which the height of the temperature is undoubtedly a most important index of the severity of the disease, there exists no such parallelism between the temperature and the nature and severity of the other symptoms as we should expect if these symptoms were caused by the increased heat of the body.

It is a matter of common observation that in the so-called typhoid pneumonias, which constitute one of the groups in which the mortality is excessive, and which are of gradual onset, the temperature usually attains a very moderate elevation, 101° to 103° F.

A large dose of quinine given in the beginning and the early administration of calomel exert a favorable influence upon the temperature.

Sometimes it may become necessary to administer internal antipyretics. Among these antipyrine, not less on account of its sedative action upon the nervous system than on account of its antithermic influence, is preferable. Very large doses are to be avoided, lest they depress the action of the heart.

On the continent of Europe cool bathing is resorted to in the treatment of pneumonia with excessively high temperature. The bathing exerts a remarkable effect upon the nervous system; it is at once stimulant and calmative. The baths should be administered at a temperature of from 85° to 90° F., or even higher; or, in the case of strong people with high fever or severe nervous symptoms, as low as 77° F. Strümpell advises that not more than two or three baths should be administered daily, and that they should not be given at night, except in the event of threatening symptoms. Refreshing sleep is said to follow the application of the bath, with quieter and deeper breathing, and a remarkable sense of relief and refreshment. I have had no personal experience with the use of baths in pneumonia, except in the pneumonias of infancy; but I have repeatedly seen very marked benefit follow cold affusions to the head and chest in severe pneumonia of young adults with high temperature and a tendency to stupor.

A fall in temperature must not always be attributed to the action of an antipyretic drug which may have been given, since the natural history of croup-

ous pneumonia shows a decided pre-critical fall as well as the abrupt defervescence at the crisis.

It is important to relieve pain. This may be accomplished by small doses of Dover's powder, from three to five grains, or the tincture of ipecacuanha and opium in corresponding doses, repeated at intervals of three or four hours, or by hypodermic injections of morphine repeated at intervals of six or eight hours. The doses should be so ordered as to produce a slight amount of continuous somnolence. Mental agitation and anxiety are thus also avoided. Under the influence of these remedies the patient's breathing is often notably improved.

Early in the case, leeches over the consolidated lung often seem to exert a favorable influence. Turpentine stupes may be applied at intervals of four hours, or warm wet compresses covered with oiled silk may be used. Sometimes the application of an ice-bag gives relief. I believe poultices are less used at present than formerly. Certainly unless well made and carefully applied they have very decided disadvantages. The cotton jacket is a good substitute for them, or, still better, a shirt lined with light carded wool, which packs less readily than cotton. Blisters should not be used in the early stages. Dry or wet cupping is sometimes used in place of leeching.

After a time pain ceases to be a troublesome symptom, and the opiates may be diminished either in dose or in the frequency of administration. Carbonate of ammonium may now be given with advantage, partly on account of its stimulant effect upon the respiratory centre, and partly because it appears to exercise a favorable influence as a cardiac stimulant. After the defervescence, it may be replaced by the chloride of ammonium.

In ordinary cases a small amount of alcohol in the form of milk-punch or wine should be systematically administered from the beginning, and in others immediately after the subsidence of the intensity which characterizes the onset of the febrile movement. If the heart flag, alcohol is to be given liberally, the character of the pulse and the first sound of the heart being made the gauge of dosage. Strong black coffee or hypodermic injections of ether or of camphor dissolved in olive oil are to be given upon the supervention of evidences of failure in the circulation. Strychnine is useful as a respiratory stimulant and may be administered hypodermically at intervals of eight or twelve hours.

If there be sleeplessness notwithstanding the administration of small doses of opiates, chloral, in doses of from seven and one-half to fifteen grains, proves a most serviceable hypnotic.

In severe cases of pneumonia I am in the habit of administering throughout the attack the mixture of one part of oxygen with two parts of nitrogen monoxide, sold in the shops under the name of Walton's oxygen. These inhalations, systematically repeated at intervals of one or two hours, and sufficiently prolonged, have appeared to exercise an admirable influence upon the respiration and circulation and are often, in cases of great restlessness or agitated delirium, followed by a period of quiet sleep.

Upon the supervention of defervescence there is occasionally observed a tendency to collapse which demands the application of external heat and the free use of diffusible stimulants both by the mouth and hypodermically. If resolution be delayed or if pleural pains continue to be troublesome, flying blisters over the affected side are indicated. Convalescence is, in the absence of complications, usually short and satisfactory.

Insidious pneumonias beginning centrally, the lesion progressing little by little, are often difficult alike to diagnose and to treat. These are the so-called typhoid pneumonias. They often run a protracted course and are of unfavorable prognosis.

Death usually occurs from asthenia; sometimes from the mere mechanical circumscription of the respiratory tract, as, for example, when upon the third or fourth day after the appearance of consolidation throughout one lung, the same process is set up in the other lung. When the lesion in the second lung is extensive, the case is not usually amenable to treatment and speedily terminates in death.

MECHANICAL OBSTRUCTION IN DISEASES OF THE UTERUS.[1]

By GEORGE F. HULBERT, M.D.,
of St. Louis, Mo.

My observations of and experience with the diseases of the uterus in which mechanical obstruction, or its congener, stenosis of the canal, is considered to be the malady is so at variance with the consensus of medical opinion and practice, that I wish to make it a matter of record and open the door to criticism and correction, if such are deserved.

It may be somewhat startling to many of those men whose reports of cases and operations relating to the subject under consideration so frequently appear in our medical journals, when we say that in more than ten thousand women coming under our care in hospital and private practice, a large proportion of whom suffered from uterine disease, we have not seen a single case which satisfied us that mechanical obstruction existed or was the disease, although the phenomena supposedly attendant upon that condition were frequently observed; and

[1] Read at the sixteenth annual meeting of the Mississippi Valley Medical Association, Louisville, Kentucky, October 8, 9, and 10, 1890.

that in over three hundred autopsies in which the pelvic contents and conditions were carefully examined, we have not found a single case which positively demonstrated that during life mechanical obstruction existed—that condition which has occupied so much of the time and attention of gynecologists, and has been the *fons et origo* of so much operative procedure and instrumental paraphernalia.

Such being our declaration, it becomes incumbent upon us, in explanation, to present the reasons for "the faith that is in us." In doing so, we shall consider the subject under the following heads:

1. The normal or natural order of things, as related to structure and function.

2. The abnormal, pathological, or unnatural order of things, as related to structure, and the possibility or impossibility of, or interference with, the performance of function.

3. The phenomena usually considered as due to "mechanical obstruction" and their accepted explanation.

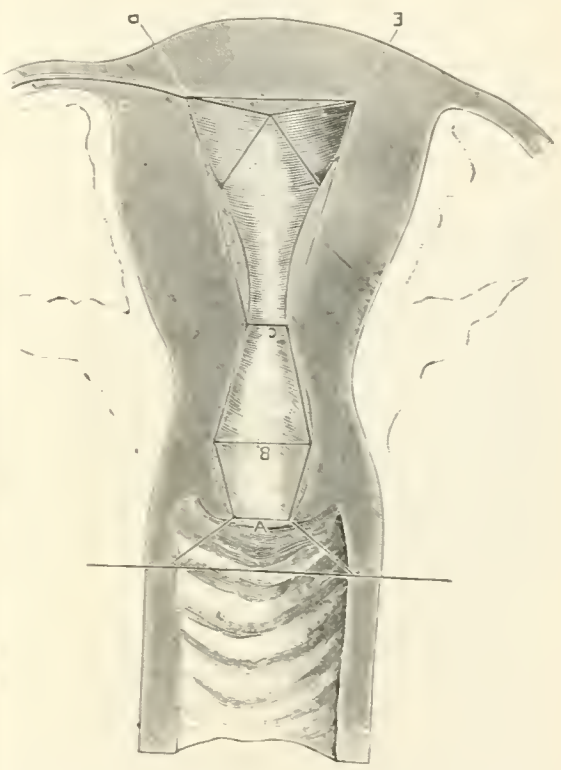
4. Our criticism and reconciliation of inconsistencies, based upon the facts and phenomena observed by us during life and in the dead-house.

5. Conclusions.

First. We may question if menstruation, as observed to-day, is a perfectly normal or natural phenomenon as far as it relates to the quantity of fluid discharged. Reasoning by analogy and from the purely physical standpoint, it certainly seems a strange straining of that universal uniformity of law and order in nature, that in the highest mammalian this particular element in the functional phenomena should be so greatly and unnecessarily overdone. But it seems from the testimony at hand that such is the fact; that at the menstrual period in women we do have a more or less free *discharge of fluid*, instead of what seemingly should be a simple elimination or excretion. The conclusion, therefore, which we must reach, is that the organ which we are considering must be competent to discharge fluids. The reason that the uterus is composed of involuntary muscle is at once plain to any one who considers its other peculiar function, gestation; but the reason for its peculiar form, the arrangement of its cavities, the complicated interlacement of muscular fibres, the dual nervous supply, and the delicately-poised position in the body is not so evident. In our search for a reason for these things, it occurred to us that the uniformity of law and order in nature might be a possible explanation, and that in the physical laws and conditions governing the discharge of fluids would be found the answer to the query. Investigation in this direction led to the conviction that the application of the conic frusta to containers presented the most perfect conditions in order that the greatest velocity and quantity of discharge of fluids be attained. The laws and principles involved in this particular domain of physics presented a striking adaptation to the uterus, and seemed to offer a clear explanation.

By reference to Fig. 1 this application may be seen. We have four apertures of exit, at D, E, C, and A. At the aperture of the Fallopian tubes: at the internal os or sphincter, extending down to the line B; and at the external os extending into the vagina, we see the principle of the conic frusta applied with peculiar perfection. As to form, we see this at the internal os, C. It is also to be observed that that part of the entire canal which approaches each

Fig. 1



aperture is more or less perfectly tubular in form, thereby assuring a *column* of liquid above and pressure in the axis of exit. We also find that each aperture is provided with a well-developed muscular sphincter, covered with a thin, closely-adherent mucous membrane, which insures the even closure of the lips of the apertures, save at the external os, where other principles come into play, namely, that of aspiration by the contact of the os with the vaginal mucous membrane, and the elastic play insured by the uterine ligaments, the movements of respiration, and the general movements of the body.

In estimating the capacity of the normal uterus by means of the above principles of hydrodynamics,

it was found that the uterus was capable, with one-fourth of an inch aperture at the point of exit and one inch depth of cavity, with the resultant pressure of the column of liquid contained therein, of discharging 0.64541 cubic inch per second, or 38,624.4 ounces during the twenty-four hours. Reducing the diameter of the aperture to one-thirty-second of an inch, we find a capacity equal to 603.493 ounces for twenty-four hours. In menstruation the average flow for twenty-four hours is from three to five ounces of fluid with a temperature of 100° Fahr. and a specific gravity of 1.055. This gives the uterus a capacity to discharge about 600 ounces more than it is required to discharge, with an aperture of one-thirty-second of an inch.

It is also necessary to recall the peculiar arrangement of the muscular elements of the uterus, namely, longitudinal, oblique, and transverse muscular fibres intimately interlaced, establishing conditions which, in the presence of proper innervation and nutrition, insure the certainty of play of force. With peculiar strength is the fact of the dual nerve-supply, namely, a direct spinal supply to the cervix and a ganglionic supply to the body of the uterus, brought to mind in our application of these principles. The cervix, responsive to immediate reflex influences at the internal sphincter, especially concerned in permitting exit and entrance under proper conditions; the body, under ganglionic innervation, concerned in the wonderful phenomena of creative energy, in the to-and-fro play of its forces annuls sufficient of the necessary antagonism to establish equilibrium in the performance of function, and menstruation becomes an unconscious experience in the life of women, save to the sense of sight.

In the circulatory arrangement we see a still further application of our principles, in that the quantity of fluid is governed by a power inherent in the organs, so that in the presence of equilibrium of all else the supply and discharge are under perfect control.

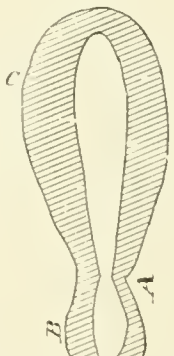
As a last point under this head, we will recall the *rhythmical intermittent discharge* of the fluid during menstruation, dependent upon the physiological action of the uterine circulation. It may be well termed the evidence of a *uterine respiration*, so to speak, by which the life of function is maintained.

Second. From a pathological point of view, the conditions accepted as being the cause of mechanical obstruction are those that produce narrowing or closure of the uterine canal. These so far as described are flexions, conical cervix, pinhole os, and congenital or acquired partial or complete stenosis, the latter being synonymous with atresia. Some consider displacements without distortion of the canal as mechanical obstruction, but the presence of the open canal makes such claims inconsistent. However, those who have taken the latter position have made progress, and, in reality, their inconsistency has brought them nearer the truth.

The condition of flexion of the uterus has generally been considered the typical one for mechanical obstruction; and we are presented with the flexed rubber tube as illustrating the condition. But this fails to illustrate the conditions as they actually exist.

The manner in which a flexion is brought about is, we believe, in perfect accord with mechanical laws. Given that vicious constitutional condition, of which the local expression is debility of the uterine tissue and its supporting ligaments, called *softness* by Graily Hewitt, without which the development of a flexion is impossible, the first step is an excessive amount of blood in the parenchyma of the organ and its adnexa. This means lack of muscular tone and increased weight, causing the uterus, as a whole, to rest on the posterior and lower part of the pelvic floor; or, if the conditions are so fortunate, on the lower uterine ligaments. The descent persisting and increasing, owing to the angle at which the cervix meets resistance, or to pressure on the fundus, the cervix or body must move either forward or backward, and the result is a flexion. This is a matter of time; there is not sudden violent bending of the uterus, as occurs in the rubber tube, and the degree of bending is determined by the conditions of the uterine tissue. This bent position having been produced, a process of atrophy at the concavity of the angle, and of elongation and hypertrophy at the convexity, at once begins, and *pari passu* with the bending the atrophy and hypertrophy proceed, so that in the process, when completed, that factor which is the essential cause in producing closure in the rubber tube, namely, the V-shaped wedge of tissue at the convexity of the angle, is not present. This is shown by the accompanying cut (Fig. 2).

Fig. 2.



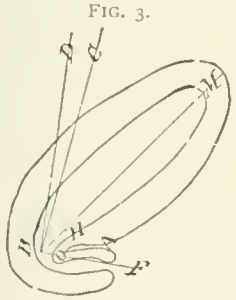
At *A* is seen the indentation where the normal tissue has atrophied. *B* and *C* show the hypertrophy in the posterior wall.

The hypertrophy of the posterior wall is due, no doubt, to the constant efforts exerted to accomplish the function of menstruation under the changed conditions, and also by the constant irritation produced at the point of impact on the floor of the pelvis.

The atrophy of the anterior wall at the angle is in accordance with the well-known effects of pressure and interference with nutrition. The disappearance of this wedge of tissue in the anterior wall at the site of the angle, in the final rearrangement and adaptation for function, results in the longitudinal and oblique fibres, anteriorly, having instead of two points of departure in contracting, as at the fundus and extremity of cervix, three points, namely, from fundus to angle, and from the angle to the extremity of the cervix, the ultimate result being the same in either case—pulling forward of the anterior segment of the tissue at the site of the angle. The posterior segment would follow, as it does in the rubber tube, on the simultaneous contraction of the longitudinal and oblique fibres, *but for the interposition of the lateral segments, which does not occur in the rubber tube.* Thus it is seen that with a fairly coördinate action of all the fibres in any particular transverse plane of the uterine body closure of the canal is simply impossible. Any angle in the direction of the canal must be more or less straightened, this result being dependent upon the area of uterine tissue brought into action. A perfect *en masse* contraction of the organ must produce more or less straightening and patency of the canal dependent upon the amount of force exerted.

This is illustrated by Fig. 3:

FIG. 3.



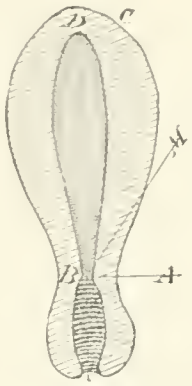
Extreme degree of flexion—45°: *O*, showing the atrophy in the anterior wall at the site of flexion; *M*, *O*, *A*, points of departure on the contraction of longitudinal and oblique fibres in the anterior wall. The interposition of the lateral wall between the anterior segment at *O* and the posterior at *B* makes it impossible for the inner surfaces at *A* and *B* to come in apposition, save by a dominant contraction of the sphincter fibres.

To this antagonism of forces we can attribute the fact that in the most acute flexions the canal is not bent at an angle, but maintains the direction of the segment of a circle.

In our examinations to determine the degree of flexion we frequently deceive ourselves, and speak of acute angles. As a matter of fact, it is rare that we meet with a flexion more acute than a right angle, and in an acute-angled flexion during life we not only would be sure to find the fundus in the position of an anteversion, but the os would be toward the meatus urinarius.

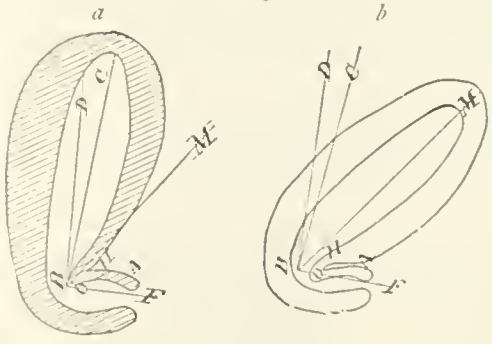
Fig. 4 illustrates what would be present in a right-angle flexion:

FIG. 4.



If the central line, *D B* (Fig. 4), of the fundus was brought forward, and placed on the line *C B*, Fig. 3, we would have the fundus about in the normal position in the body. Now, moving the central line of the cervix forward so that it rests on *B*, *F*, we would find that the prolongation of this line would make its exit at the anterior edge of the anus. This would represent a flexion with a right angle. Now place *D B* on *M B* (Fig. 5, *a*), and the central line of the cervix on *B F*, and we have an angle of 45°. In this case a prolongation of the central line of the cervix would pass out through the posterior commissure of the vulva.

FIG. 5.



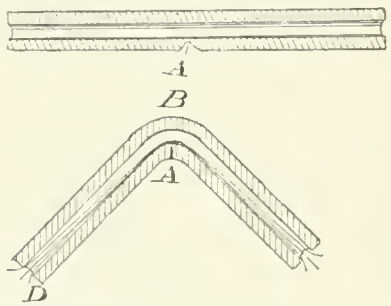
The last illustration shows an extreme degree of flexion, which is found only in the minority of cases. The proof of the disappearance of the tissue at the concavity of the angle of flexion is found in autopsies, and is demonstrated by straightening the bend and comparing the anterior and posterior walls. We have seen some specimens in which the healthy tissue at the concavity was only one line in thickness.

In order that the rubber tube should accord with the existing conditions, it is necessary to select one corresponding in the thickness of its walls and in its calibre with the normal uterus at the internal sphincter, one which is elastic, one in which there is some means of producing the effects of the longitudinal and oblique fibres, and, lastly, one in which a sufficient amount of the wall at the concavity of the angle shall be removed corresponding to the absorbed and atrophied tissue at the site of the angle in the deformed uterus. This done, the bent rubber tube will in a fair degree illustrate what takes place at menstruation in a flexed uterus.

The action of the longitudinal fibres, as far as the anterior wall is concerned, can be produced by passing a few threads through the calibre of the tube, fixing it in the angle desired, which is usually not more acute than a right angle, and making traction on the threads in the line of each arm of the bent tube. It will be found that the obstruction even with this imperfect arrangement will be overcome, and that water will flow through the tube.

This is illustrated by Fig. 6:

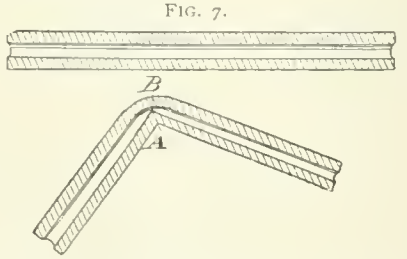
Fig. 6.



The upper illustration shows the prepared tube; at *A*, V-shaped wedge of the anterior wall removed. The lower illustration represents the same tube, bent at a right angle, and the effect produced by traction on the threads in the line of each arm of the bent tube. The arms are firmly fixed in position in any sustaining apparatus, as a glass tube is slipped over and held by an assistant.

Fig. 7 illustrates the usual faulty method, save that the tube is of the proper dimensions to use in the above experiment.

Fig. 7.



The closure on bending at *B* is readily understood, and the effect of removing the wedge-shaped piece of the anterior wall at *A*, as well as the influence of the longitudinal threads, is possibly better appreciated by the comparison.

From the foregoing we conclude that in the abnormal deviations of direction which are found in flexions, nature in her conservatism still utilizes the principles and agencies present in the normal state, and thereby perpetuates the operation of natural laws and insures the performance of function.

Only by this conception are we able to account for the phenomena of normal menstruation so frequently found, certainly in fifty per cent. of women who have well-marked flexions. We have frequently seen women in whom it was possible to pass into the uterus only a small wire probe, who had at no time suffered from inconvenience during the menstrual flow.

Upon the other conditions productive of mechanical obstruction there is this observation to make, namely, that *at times there exists the capacity to discharge fluid blood*, save in only one condition—*atresia*. All that the uterine canal can justly be called upon to permit to pass through it is *fluid blood*. If the passage of clots, mucous plugs, shreds of membranes, etc., are the evidences needed to establish the conditions for mechanical obstruction, then we are, indeed, undone. We respectfully submit that such a demand is unreasonable, illogical, and unscientific. We conclude, therefore, that the passage of fluid blood is positive proof that there exists a capacity in all the above conditions, save that of atresia, for the performance of function.

Third and fourth. Such being our conclusion, how do we account for the symptoms usually ascribed to mechanical obstructions, namely, pain, intermittent and scanty flow, relief from pain when the flow is present, and inability to pass the uterine sound? The most radical of those who claim that flexions produce mechanical obstruction, freely admit that where menstruation is normal and painless obstruction is not present. Stenosis being the condition considered necessary, by the "obstruction philosophy," in the absence of the diagnostic symptoms mentioned above, there is, consequently, no stenosis; hence these diagnostic symptoms must be explained.

We have seen from what has been presented the importance of that harmonious, perfect, involuntary, and unconscious rhythm of circulatory, muscular, and nutritive action found in health. As the dominant energizing factor we must look to the inherent quality of nutritive and nervous capability, and to this alone; and in grasping the full meaning of this we must go back to the quality of protoplasm before our position becomes rational. This is a universal principle so frequently lost sight of by us as gynecologists, that it is no surprise to see so much error and disappointment in our therapeutics, be they surgical or otherwise.

We must go to the nervous system, especially the sympathetic, for the all-governing factor: to nutrition, as a whole, we must go for stability of function. The nerve-tone coupled with the resultant nutritive activity and power, both impressed, under favorable environment, with the capacity for a higher standard, determines what shall be the future of every organism or part thereof.

A woman born with and maintaining a standard degree of health will never be cursed with any of the conditions we are considering. But in those who are born without the standard, or who, by the vicissitudes and accidents of life, depart from perfect health, in proportion to the deviation we will find the liability to and acquisition of these conditions. In these deviations from the standard degree of health we find lowered nerve and nutritive tone, manifested by irregular and erratic innervation, resulting in irregular, incoördinate action, increased irritability, irregular circulation and muscular action, pain, spasm, and relaxation, alterations of secretion, rapid exhaustion, slow recuperation, imperfect repair, insuring debility, fatigue, pain, and disorder in the accomplishment of function. These are the real factors in the dysmenorrhœa of so-called mechanical obstruction. These, and not stenosis, are the disease.

In the functional antagonism between the cervix and the body of the uterus we find the immediate cause of all the symptoms attendant upon mechanical dysmenorrhœa. Irritation or dilatation of the cervix produces contraction of the cervix. This physiologically and anatomically demonstrable fact, which, if sought for, is always found antedating and associated with mechanical dysmenorrhœa, when followed to its reasonable and logical conclusion, proves that mechanical obstruction, as at present generally accepted, does not exist save in that condition termed atresia.

The constitutional condition means increased local irritability and lowered nutrition. This begets irregular and spasmodic muscular and circulatory action, with altered excessive or scanty secretion and excretion. The excessive flow, the blood-clots, the membranes, and the mucous plugs are due to the influences mentioned, and their expulsion produces severe suffering. Such cases are used by some as an argument in support of the idea of mechanical dysmenorrhœa, especially when a flexion is present. It is unnecessary to answer such arguments. It would be perfectly consistent for these men to assume mechanical obstruction as a disease, in the delivery of a fœtus. But given menstruation with fluid blood as the substance to be expelled in a woman who presents the symptoms of mechanical dysmenorrhœa, what facts will aid us in the present discussion? Excluding atresia, it matters not what the local condition is, we find the general deviation from the standard degree of health. A fat and apparently well-nourished woman may present symptoms at her menstrual period similar to those presented by another woman in the opposite condition of general health. In the first instance, innervation, motor power, is at fault; in the second, the fault is in both innervation and nutrition. In both the local conditions are alike. Now, take either of these women and place her under methods of treatment that will allay irritation, produce coördinate action, and improve the general health, and we find that *without any local treatment* all the symptoms indicative of mechanical dysmenorrhœa disappear, and still the flexion, pinhole os, elongated cervix or stenosis, remains. Let the woman return to the original diseased condition, and the symptoms of mechanical dysmenorrhœa again appear. Furthermore, in the worst cases, in which the flow is usually very scanty, we find that in spite of the *persistent stenosis*, as they approach the standard degree of health the flow increases and the suffering decreases and eventually disappears. Manifestly, we must look elsewhere for the cause of the symptoms, and we find it in lowered nutrition and increased irritability, expressed by hyperæsthesia and erratic muscular and circulatory action. It is nerve-ache, muscle-ache, nerve-tire, muscle-tire. It is the cry for quietude, harmony, and rest from the ceaseless and persistent wants of the physiological rhythm of forces. That the local condition in its development has no influence on the systemic we do not affirm. In the progress of every case the time arrives when the local condition, by reflex influences, becomes a very important element in the process: first, from general to local; second, from local to general, until the poor sufferer cries out in agony, afraid to move, afraid to laugh, afraid to lie down; tenderness and pain in all parts of her body, and in constant fear of the monthly onslaught of what should be to her an unconscious relief. This is not enough, it seems, but she must be further accused of carrying around with her a disease called "mechanical obstruction," and be subjected to sponge-tents, and incision and divulsion of the cervix, followed by the use of a stem-pessary.

Especially bearing upon the interpretation of the pain in conditions of supposed mechanical obstruction, we desire to direct attention to a condition in which the pain is of the same character and in which mechanical obstruction cannot be present, namely, the "after-pains" of parturition. We are of the opinion that as far as the location, character, and manner of onset of the pain are concerned, there are no differential features between the pain of mechanical dysmenorrhœa and the "after-pains" of labor, yet in the presence of only *fluid blood* severe "after-pains" frequently occur. There being

no stenosis after a parturition, the severity of "after-pains" in the absence of blood-clots is considered dependent upon nervous, nutritive, circulatory, or muscular influences, even by the most radical supporters of mechanical obstruction in menstruation.

In considering the question of spasm of the internal sphincter as a factor in producing the phenomena of mechanical obstruction, we are impressed with the desperation of many in striving to retain the mechanical idea of dysmenorrhœa. Correctly understood, this frequent and ever-ready action of the internal sphincter serves but to establish our position in antagonizing the mechanical idea. The presence of the spasmodic element is proof positive of unnatural and incoördinate muscular action, as well as increased local irritability. This, coupled with the antagonism existing between the cervix and body of the uterus, readily explains why during menstruation, the spasmodic action should occur, and also why there is no flow until the spasm is relieved. In spasmodic or neuralgic dysmenorrhœa the menstrual flow is almost *nil*. This is not due to a damming back by the spasmodic closure at the sphincter, but is due to the fact that there is no menstrual fluid in the cavity of the uterus, and it is only when coördinate action is accomplished that blood exudes from the endometrium. This is readily proven by the introduction of a tube into the uterine canal during the menstrual period, insuring beyond a doubt patency of the canal.

The diminution or disappearance of pain when the flow is established is now readily understood, when we say that it is due to the rhythm of forces finally accomplished, to nervous, muscular, and circulatory factors, within the tissues, and not to the forcible expulsion of retained fluid. The failure to pass the probe or sound is a mere matter of diagnosis and dependent upon the hand that manipulates it.

Finally, we appeal to post-mortem investigations. Any one who has labored in the dead-house, investigating the pathology of those conditions which are considered active factors in the production of mechanical obstruction will meet with one stubborn fact, namely, that the conditions found after death are far different from those that would be expected from the severity of the symptoms during life. Consider, for instance, endometritis, and in the dead-house the specimen, macroscopically, is hardly distinguishable from one obtained from a subject who had never during life suffered from such a disorder. Microscopically we find the difference, and in the vast majority of cases are forced to conclude that this difference is more a functional than organic one. Take also any specimen and study the subject of stenosis of the canal, and how often, unless there is stenosis from scar-tissue in the mucous tissue lining the canal or congenital atresia, will you find a contraction that fluid blood would not find its way through; certain it is that fluid blood will travel through the capillary system, and the uterine canal, save in atresia, has a diameter equal to at least several capillary vessels. We also find in post-mortem examinations that the uterine canal, even in the presence of great deviations in surrounding structures, or extreme distortion and displacement of the organ, is free from acute angles, and that the cavity is tubular, especially at the site of the internal sphincter. These facts are readily proved by sections in any direction, and are readily accounted for if we accept the influence of the muscular elements and correctly interpret the mechanical laws at work in the form and structure of the uterus in their relation to the performance of function.

In the attempted demonstrations of the existence of mechanical obstruction by its supporters, the fact that they were dealing with a *dead* organ seems to have been lost sight of; for in no other way can we explain the usual methods of attempting to prove mechanical obstruction *during life* by forcing a *lifeless flexed uterus* into a greater degree of flexion, for even dead as it is it will not remain in the forced position. It would seem unnecessary to remark that pickled specimens are not suitable for demonstration, either affirmative or negative, yet they are frequently presented as showing the state during life.

The therapeutic measures which are successful in relieving and curing mechanical dysmenorrhœa demonstrate beyond all doubt the correctness of our position. And in using the expression therapeutic measures, we wish it distinctly understood that we exclude all local, surgical, or mechanical treatment to relieve the supposed stenosis of the canal. The use of reconstructives, such as good, palatable food, the elegant gluten and malt preparations, and the hypophosphites and bitter tonics, for the purpose of restoring the standard nutrition; the employment of narcotics, anodynes, antispasmodics, such as opium, compound spirit of ether, antipyrine, viburnum opulus and viburnum prunifolium, alætris farinosa, helonias dioica, cimicifuga, scutellaria, laterifolia, and gelsemium; the valuable anti-congestive drug, hydrastis; the coördinating muscular tonics, ustilago maydis and quinine; and last but not least, electricity, are attended with results eminently successful. The intelligent and persistent use of these means will, in the absence of atresia, cause all the phenomena of mechanical obstruction to disappear, while the local deviation, as far as form and displacement are concerned, may remain. The local state, as far as secretion and function are concerned, will be restored to a normal condition.

Furthermore, it is a matter of daily observation,

that all surgical and mechanical methods of treating dysmenorrhœa which are not assisted by pronounced improvement in the systemic, nervous, and nutritive forces of the patient are ineffectual.

We respectfully submit the following conclusions:

1. That in the natural order of things we find the uterus in form and structure endowed with a capacity for the performance of the function, menstruation, so far in excess of any legitimate demand, that with a diameter of the canal of one-fourth of an inch at the sphincters the excess is 7724.8 times the demand, and with a diameter of one-thirty-second of an inch the excess equals 120.7 times the requirement.

2. That in the pathological conditions considered essential for mechanical obstruction we find that the conservation of force so regulates the conditions that this capacity is not abolished, but persists in an eminent degree, so that in the presence of the normal physiological energy the function is accomplished, unless there is atresia.

3. That the phenomena considered as dependent upon mechanical obstruction are not due to the forcible expulsion of retained fluids through the uterine canal, but are produced within the tissues, and are dependent upon *disturbed* rhythm of physiological forces evolved by abnormal innervation, muscular action, and circulation.

4. That the demand upon the uterus for the passage of blood-clots, membranes, mucous plugs, uterine sounds, sponge-tents, uterine dilators, etc., in order that the diagnosis of mechanical obstruction may be made, is not only vicious in the extreme, but irrational, illogical, and unscientific.

5. That the correct and rational interpretation of the testimony offered by symptomatology, pathology, and therapeutics, removes mechanical obstruction from the domain of gynecology as a demonstrable fact, save in atresia uteri.

3026 PINE STREET.

THE MEDICAL EXPERT.[1]

BY J. T. ESKRIDGE, M.D.,
OF DENVER, COLORADO.

AT a recent meeting of the Medico-Legal Society of Denver, the President appointed several committees to report before the approaching session of the Legislature of Colorado, on certain necessary changes in our laws in relation to the establishment of a State Lunacy Commission and a State Board of Charities. Committees were also appointed to consider and report on the medical expert, the care and protection of our insane, prison reform, and the necessary statutory changes to make official autopsies more scientific and thorough.

[1] Read before the Medico-Legal Society of Denver.

These several committees are expected to report on the various subjects committed to them, so that the Society's Committee on Legislation, after hearing the discussion by members of the Society, may be prepared to enter upon their duties, and endeavor to secure legislative enactments in accordance with the Society's wishes.

No one who has compared the laws of many of the Eastern States of this country on the above subjects with the meagre legislation, or the absence of legislation, on the same in Colorado, can doubt the propriety and timeliness of the Medico-Legal Society's action upon these neglected but important subjects.

As a preliminary to the report of the Committee on the Medical Expert, I wish to consider the status and necessary qualifications of the medical expert most in demand by the majority of the legal fraternity, together with some suggestions looking to a partial prevention of the confusion resulting from the present method of employing medical expert testimony.

According to decisions of various courts of law, anyone who possesses special knowledge of medicine and subjects relating thereto, whether he be a graduate in medicine or not, and regardless of the school of medicine to which he belongs, may be called to testify in court as a medical expert. It seems, then, impracticable for any State to enact a law to prevent either side of a case from calling any medical witness desired, and the jury must be left to judge of the fitness of the expert and the value of his testimony.

There are several causes which aid in producing the unsatisfactory results obtained by the present method of using medical expert testimony. In the majority of instances the attorney for the plaintiff secures experts that best serve his purpose in the case, and the lawyer for the defence likewise endeavors to fortify his side of the case by the testimony of witnesses with different opinions. We cannot blame the lawyer, whose whole training has been to win the cause of the client rather than to guide the case and to see simple justice done. If he can secure the services of respectable witnesses who will testify in favor of his client, it seems to him proper and right. He leaves the witness to justify his own testimony. I am loath to believe that all lawyers, or even the majority of them, are anxious to gain their cases regardless of right, but I am convinced that many bright and honest legal advocates are deceived by the misrepresentation of their clients. A lawyer once impressed with the justness of his side of a case (I do not say absolutely convinced), is in sympathy with his client, and apparently without examining into the merits of each side of the case, he seems to think and act as if every means tending

to support his side is justifiable and should be employed.

The position of the medical witness should be directly opposite to that usually assumed by legal advocates. In impartiality he should rival the most upright judge and the ideal juror. In the medical aspects of a case he should take pains to inform himself without reference to the side on which he is to testify. He is but human and should not be subjected to the slightest mercenary temptation that might in anyway bias his judgment. If the medical witness should be as impartial as the judge and jury, and I think no one will deny this postulate, he should not be subjected to temptations from which they are free. How ridiculous it would seem to allow plaintiff and defendant each to choose and pay his jurors and judge! Yet, the medical expert is required to testify to, and in a certain sense, sit in judgment upon facts which neither the learned judge nor the jury "just and true" claim to be able to understand.

The habit of separate and independent examinations by medical witnesses often leads to erroneous conclusions, because, in these days of the rapid accumulation of medical literature observation and scientific investigation, no one person can become thoroughly conversant with every department of medicine. To comprehend all the facts pertaining to a difficult and obscure case, the specialist and the general practitioner, both of medicine and of surgery, are often necessary. What one fails to observe, the other will very probably see. No two minds follow exactly the same train of thought. If the examination of a person is made by a physician subpœnaed to testify for one side, he, in the majority of instances, is alert to discover symptoms more favorable to the side that has employed him than to the opposing one. Imperfect or partial examinations are more likely to result, and the personal equation of the examiner is in greater danger of being magnified, when the examination is made separately than when the physicians examine and consult together as a board. One physician may be thorough in certain departments of medicine and not in others, or he may hold certain theories which carried to their ultimate conclusions become mere vagaries. Such defects may be partially obviated by joint examinations. The editor of the *British Medical Journal*[1] writes:

"In Leeds, the custom has, we believe, long obtained among the leaders of the profession to refuse to give expert evidence on any case until after a meeting of the experts on both sides; and this practice has worked so well that the Leeds Assizes are notable for the absence of the conflicts of scientific testimony which elsewhere have done so much to discredit such testimony in courts of law."

[1] March 1, 1890.

To meet the objections against the present system of employing medical expert testimony, Dr. Morton Prince, of Boston, in an able article entitled "The Present Method of Giving Expert Testimony in Medico-Legal Cases,"[1] makes the following suggestions:

"1. The examination of all claimants should be made by experts on both sides, but in conjunction with each other and acting as a Board. The examination should be conducted as frequently as the Board should determine. This would not prevent preliminary and individual examinations by either side.

"2. The Board of Experts after thus acting should make a sworn written report to the court in accordance with a specified form; that is, the report should contain a distinct and separate statement of the medical history, objective facts, and finally the opinion of the experts.

"3. If the Board is unable to agree on the purely objective facts (for example, whether there was or was not paralysis, loss of sight, fracture of bone, etc.), the court should, at its discretion, direct one or more official State experts to examine the claimant in conjunction with other experts, and report likewise in writing their opinions.

"4. A number of experts in each department of medicine should be appointed by the Governor, and from them the court should select experts at its discretion.

"5. At the request of either side of a case, the court should direct one or more State officials to make an examination.

"6. All experts should be examined in court as now."

It is easier to criticise the suggestions made by Dr. Prince than to suggest better ones. There are, however, many objections to State medical experts, and to their appointment by the Governor. If the appointing power rested with the Governor, it would become a part of the political machinery of the State, and candidates for positions on the Board would receive their appointment more on account of their political influence than because of scientific qualifications for the work.

Further, there would be a temptation for ambitious, but unscrupulous, physicians to seek such appointments on account of the prestige it would give them to be recognized as State medical experts. Any ignoramus in Colorado, be he a graduate in medicine or not, might be sure of such an appointment if he, or his friends, could control a few hundred votes. Men should be sought for such positions and should not seek the positions. Again, the influence that such a Board would have with a jury would be as great if composed of unqualified persons as it would be if none but the most competent men in the State were on the Board. If such a body of official experts should have no further qualifications for their positions than would be necessary to secure their appointment through political influence, it might lead to exorbitant awards or unjust punishments. It seems to me that in Colorado, at least, an official Board of experts, appointed

[1] Boston Medical and Surgical Journal, January 23, 1890.

annually or less frequently, would probably be productive of more harm than good.

Might not the benefits expected from a State Board of medical examiners be obtained by other, and less elaborate means, without incurring the objections against such a State organ? Much of the confusion resulting from conflicting expert testimony might be avoided if the court were required to name experts to testify in a given case, regardless of the wishes of the lawyers for either plaintiff or defendant, and guided solely by the qualifications of the experts for the particular case. This would not prevent the attorneys from calling physicians of their own selection, provided that no expense beyond the ordinary witness fee were incurred by the county for these witnesses The experts named by the court should have a definite fee for their services, regardless of their opinion in the case. Testimony from experts so appointed and paid would be entirely unprejudiced by mercenary considerations, and would deservedly have more weight with a jury than the testimony of physicians selected and paid by either the plaintiff or the defendant.

If we had a law making it obligatory upon the court in every case requiring medical expert testimony to appoint one or more experts, the number depending upon the importance of the case and the wishes of the counsel for each side, then the experts appointed by the court, and those chosen by the attorneys, if any were so selected, should be required to examine jointly all such persons whose claims might be under investigation, and consult together as a board. The number of examinations should be determined by the majority of the board. Individual and preliminary examinations should not be denied if consented to by the attorneys and by the person whose claims might be under investigation.

It is remarkable how infrequently physicians disagree in consultation, either in hospital or private practice, and equally remarkable how frequently physicians employed by opposing counsels disagree in their testimony on the witness-stand. Much of this difference of testimony occurs from the one-sidedness of the physician's information of a case. Were examinations made jointly and consultations held afterward, this source of error would be excluded.

The following is the report of the Committee on Medical Experts appointed by the President of the Medico-Legal Society of Denver:

1. "That it is the sense of this Society that its Committee on Legislation should endeavor to have a law enacted at the approaching session of the State Legislature empowering and requiring the judge, before whom a case necessitating medical expert testimony is to be tried, to select one or more medical experts, the number depending upon the importance of the case, the wishes of the attorneys for both sides, and upon the approval of the presiding judge.

2. "That the Board of Physicians so selected by the court be required to examine the claimant or defendant jointly as a Board, and that other physicians selected by the attorneys for either side be permitted to be present and participate in the examinations and discussions of the Board.

3. "That the physicians selected by the court be required to testify in court concerning their examination and submit to cross-examination as is now the custom.

4. "That a definite expert fee be allowed by the court and paid by the county for each of the physicians selected by the judge.

"All of which is respectfully submitted.

THE DIAGNOSIS OF EARLY ECTOPIC GESTATION.

By J. M. BALDY, M.D.,
of Philadelphia.

In following me into a discussion of this subject I wish it to be distinctly borne in mind that what I have to say is applied to ectopic gestation only in its earliest stages, namely, in that period when the rupture is liable to take place from the tube into the broad ligament, or into the abdominal cavity, as well as the period immediately following the rupture.

It would seem from this that I accept the views of Mr. Tait as to the pathology of extra-uterine pregnancy, and, with a few reservations, this is the fact. My whole line of argument will be based on the premises that the conception has taken place in one or other of the Fallopian tubes, or has subsequently found its way there, and has there developed. I do not wish to be understood as denying that there is such a condition as ovarian or abdominal pregnancy, but for our present purpose we may safely ignore that phase of the question altogether, because in the early stages of the disease with which we are dealing the three conditions could hardly be differentiated. It is certain that an overwhelming majority of the cases are tubal in their incipiency, and if an occasional case is either of the other two varieties, it cannot make the slightest difference from a diagnostic and therapeutical point of view.

In this discussion I propose to ignore, to a great extent, the ancient literature of the subject. However valuable this has proven in times past in establishing the pathology of extra-uterine pregnancy, it is to-day of far less value from the point of

view of this paper than the experience and literature of the last few years. I infinitely prefer the testimony of men who have made their observations with a pretty clear idea of the pathology and frequency of this and allied diseases, to that of men who were groping in the dark with little or no idea of this or any of the many diseases with which it may be and has been confounded. With the recent data, then, to supplement my own personal experience of more than twenty cases of early ectopic gestation, I shall be satisfied to draw my conclusions.

The symptoms of this disease have been variously classified, and it is claimed that if a certain number of them be grouped together in the same patient, the presence of the abnormal gestation is assured. In considering these symptoms we will take them as nearly as possible in the order of their importance.

Menstruation.—This may be absent for one or two periods, and then a spurious flow appear which is at first lighter and finally darker in color than normal. It is irregular, prolonged, and contains, after awhile, clots and shreds. There may be no missed period at all—simply a prolongation of the normal flow, with the above characteristics. I have had patients in whom this spurious menstruation did not appear at all; in whom there was neither a scant nor prolonged flux. To a great extent this depends on the period in which the patient is seen; the earlier, the less likelihood of irregularities. Often the patient gives a history of similar irregularities, and one is very apt to be misled by this fact.

Pain.—This pain is of a somewhat different character from other pains to which women are liable. Early in the growth of the gestation-sac the pain is slight, and occurs at long intervals, and as a rule not much notice is taken of it. Often it disappears altogether for a few weeks, and would be forgotten but for its reappearance in redoubled force. It is intermittent in character, cramp-like, becoming more and more severe, and more and more frequent. At times it becomes so severe as to cause syncope. Its situation is almost invariably pelvic, and low down in the abdomen. It can be safely said that this symptom is invariably present. As a rule, it is the one thing which forces the patient to seek the advice of her physician. Of all the individual symptoms this one has proven of most value to me in recognizing the true condition. This almost characteristic behavior of the pains in connection with the behavior of the menstrual discharges when they are abnormal should always put one on his guard, and force him at least to weigh carefully all the *pros* and *cons* before dismissing the possibility of ectopic gestation.

Expulsion of decidua.—The decidua may be thrown off in the shape of shreds, and mixed with clots of blood, or, which is more usual, after a few days the shreds may come away in one good-sized mass. This symptom is theoretically of the greatest importance, and when it is demonstrated is conclusive (of pregnancy). Practically, its value is in the majority of cases lost. As a rule, we must depend on the statements of the patient in regard to the matter, and these statements are too often worthless. I find that patients do not observe closely enough, or are so ignorant as not to be able to distinguish between blood-clots and other things. Again, the decidua is often lost in the water-closet or in a vessel-full of clots. I have known women to declare they were discharging shreds, when a careful examination failed to reveal a sign of one. Taking it all in all, I do not attach much value to this sign—realizing, however, its great importance when it can be properly demonstrated. Its absence is usually in the early weeks of the disease.

General signs of pregnancy.—As a rule, these are the reflex, gastric, and breast symptoms of normal pregnancy, as well as the bladder and rectal disturbances of the same condition. The same symptoms may be present in women who are not pregnant, and may arise from almost any cause of irritation in the genital canal, and are only too frequently present in such diseases as ovarian cyst, pyosalpinx, etc. Standing alone they are worthless for determining pregnancy, especially the extra-uterine variety.

Period of sterility.—As a rule, the patient gives the history of having had a child or miscarriage some years previously, and of being sterile since then. This is not always the history, however, as some women conceive with the fœtus extra-uterine soon after the first pregnancy.

Vaginal discoloration.—The vagina almost invariably has the usual discoloration of pregnancy.

Cervix.—The cervix is usually enlarged and soft, and the os is patulous; but I have noticed an absence of these symptoms in several cases, and they cannot be considered as at all constant.

Body of uterus.—The fundus is enlarged and softened, and usually crowded either far forward against the pubic bone or pushed to either side. It is more or less immovable. Like the cervical signs, however, these conditions are not constant. I have studied patients for several weeks at a time, in whom the uterus was normal in every particular, trying to arrive at a diagnosis, and yet ectopic gestation was finally proven to be present.

Uterine appendages.—At times an examination of the appendages of one side is absolutely negative, while on the opposite side a tense, adherent, tender cyst is present. In several cases I have found this cyst almost in the median line, posterior and apparently so continuous with the cervix as to make

it impossible to find any dividing-line between them. In one case the fundus was so high and so far back as to seem to be a part of the cyst. On the other hand, cystic masses (apparently characteristic) will be found on both sides, one proving to be an ovarian cyst, an ovarian abscess, a pyosalpinx, or a dermoid cyst, the other being demonstrated to be a tubal pregnancy. All these conditions I have seen, and have studied with the specimens in my hands. The local condition is so varied and deceptive that only corroborative evidence can be obtained from it. The ectopic gestation-cyst, if kept under observation, increases very perceptibly in size from time to time, but it is exceedingly dangerous to wait and watch for this symptom.

Pulsation of the cyst.—I have studied the disease with reference to pulsation, and in spite of what others have said as to its importance, I have been unable to find the slightest thing characteristic about it. The pulsation is present in so many pelvic conditions, especially in distended Fallopian tubes, that I have found it worthless as a diagnostic sign in this disease. In proven cases of ectopic gestation, in my experience, it was present in some and absent in others.

Ballottement.—I have never been able to observe this sign in any case, nor have I seen a specimen earlier than the third month in which I think it could have been demonstrated. The number of cases in which it is claimed that it has been observed is small, and to me it is of very doubtful value as a diagnostic aid.

The patient considers herself pregnant.—In the majority of cases that I have seen the women did not think they were pregnant, or at least were very uncertain when questioned on this point. Only two or three of my patients stated positively that they thought themselves pregnant, and we all know how often women think themselves so when they are not. I cannot believe that this point is of much value in diagnosis.

Temperature and pulse.—A number of times I have noticed a persistent and considerable rise of temperature and increased pulse-rate, and the patients have occasionally complained of feeling chilly. The elevation of temperature is due, no doubt, to the local pelvic inflammation which so often accompanies this condition, and which causes the adhesions almost always met with.

When we come to the period of rupture, symptoms of great pain, followed by collapse, and all the signs of concealed hæmorrhage, make the presumptive diagnosis easy, especially when taken in connection with the past history.

It would be natural to suppose that if a number of these symptoms presented themselves in the same patient a diagnosis of extra-uterine pregnancy could readily be arrived at. Such is the belief of some of the profession. Reeve[1] states that "in a patient presumably pregnant, having had more than one such attack as this (he refers to the paroxysmal pains), and having a tumor to be felt *per vaginam*, there could scarcely be a doubt of the existence of extra-uterine pregnancy." My own experience has taught me the fallacy of this, and I am coming more and more to regard my position taken in a previous paper[2] as the true one. In that paper I made the three following propositions:

1. In a certain proportion of cases of extra-uterine pregnancy, in the early stages, the diagnosis is easy and unmistakable.

2. In a certain (quite large) proportion of cases sufficient symptoms are present more than to warrant a diagnosis of extra-uterine pregnancy, such a pregnancy not being present.

3. In a certain other proportion of cases the symptoms, until rupture has occurred, are entirely wanting, or are of such dubious character as in no-wise to warrant such a diagnosis.

The following history is that of a patient who passed under my observation:

CASE I.—Mrs. X., aged twenty-six years; married for seven years. Had one child six years ago. Puerperal trouble followed confinement, and she has not been pregnant since. Two and a half months ago she missed her menstrual period, and soon began to develop symptoms which made her think she was pregnant. In the course of about six or seven weeks she began to have a bloody vaginal discharge, which finally contained shreds and clots. About this time pains, which had been present in slight degree, became severe and paroxysmal. On account of the bleeding and pain she applied to me for advice. On close questioning she acknowledged having passed a mass, but was doubtful whether it was blood-clot. A vaginal examination revealed a softened cervix, a slightly-enlarged uterus, with a tense, adherent, tender cyst on the right side, the uterus being crowded to the left. A diagnosis of tubal pregnancy was made, and the gestation-sac removed two days afterward.

This case presents a line of symptoms which apparently could lead to but one conclusion, and so the event proved. But contrast this case with the two following, which occurred in my practice.[3]

CASE II.—The patient presented general and reflex symptoms of pregnancy, such as swollen and painful breasts, containing milk; morning nausea; enlarged abdomen; frequent micturition; constipation, etc.; and had missed one or two periods. The patient thought herself pregnant, though she had not been pregnant for some years. There was

[1] American Journal of the Medical Sciences, July, 1889.
[2] Medical Record, September 21, 1889.
[3] Ibid.

irregular bleeding for a week or two, with colicky pains in the abdomen, and the passage of blood and shreds *per vaginam*. Examination showed a cystic tumor to one side of the uterus, painful to the touch. The patient was seen by Dr. J. Price, and several other men, all of whom concurred with me in the diagnosis of undoubted extra-uterine pregnancy. Several days afterward an operation disclosed an ovarian cyst as large as an orange.

Case III. presented general and reflex signs of pregnancy almost the same as in Case II. She had not been pregnant for years, when she missed a period; had profuse bleeding with clots and shreds, and severe pelvic pains of a colicky character. Examination disclosed a pelvic mass at the side of the uterus, evidently a distended tube. A diagnosis of extra-uterine pregnancy was made by Dr. Kynett, several other men, and myself. Operation in a few days by Dr. Penrose disclosed pyosalpinx.

The following cases simply emphasize what my own cases prove:

Case IV.—Mrs. D.;[1] a patient of Dr. Weeks, of Trenton, N. J.; married for four years; never pregnant; menses always regular, and not painful. One week after her January period she noticed dull pain in the lower part of the abdomen, followed in another week by sick stomach and all the symptoms of pregnancy. Her menses were absent for six weeks, when she was suddenly seized with severe pain and a flow. The woman finally took to her bed. The discharges seen by both doctor and nurse were lochial in character, and contained shreds. A tender cystic mass was found to the left and posterior to the uterus; the fundus was crowded forward and to one side. A diagnosis of extra-uterine pregnancy was arrived at, and I was asked to see the patient. I found everything as narrated, and verified the diagnosis. Two days later abdominal section disclosed a large pelvic (intra-peritoneal) abscess. The Fallopian tubes and ovaries showed no signs of having been impregnated.

Case V.—Mrs. K.,[2] a patient of Dr. B. C. Hirst, aged twenty-five years. Her last child was born two years ago; menses were absent for two periods, but had returned some time before being seen by Dr. Hirst. History of discharge of clots and membrane, with great pain in pelvis and abdomen. Examination showed the uterus enlarged, and displaced to the right side; os patulous; and a tumor in left broad ligament the size of an egg. Extra-uterine pregnancy was diagnosed. At the operation which followed a broad-ligament cyst was removed. The woman afterward passed remnants of an abortion.

Dr. Joseph Price,[3] in a patient sent to him by Dr. Garrett, of Germantown, found a mass on the left side of the pelvis as large as a three months' uterus. The woman had been married for ten months; the menses ceased three months after marriage, and she had all the symptoms of pregnancy. There was absence of two periods, followed by hæmorrhage and pain. Extra-uterne pregnancy was diagnosed. Abdominal section revealed a small suppurating cyst of the right ovary, with an adherent hydrosalpinx.

Dr. H. C. Coe[1] reports the case of a woman whom he saw in consultation. She had missed two menstrual periods, and presented the subjective symptoms of pregnancy. One day she had an attack of violent pain in the abdomen, with evidences of collapse. A mass was found on the right side of the uterus, which gradually increased in size week by week. She had a bloody discharge from the vagina. A sound was passed into the enlarged uterus a number of times, and both the galvanic and faradic currents were applied. The uterus was enlarged, the cervix soft, and the os patulous. The tumor was fixed and fluctuating. Finally, she had another attack of pain, with apparent collapse. Extra-uterine pregnancy was diagnosed. Abdominal section revealed a normally-pregnant uterus, with a large adherent ovary on the right side.

Dr. G. W. Johnston reports[2] the case of a patient, aged twenty-two years, who, shortly after the cessation of a monthly period, began to suffer from nausea, frequent micturition, and colicky abdominal and pelvic pains. Her breasts were tender, the uterus enlarged and anteposed; on the right side of the uterus and posterior was a round, exquisitely tender, semi-fluctuating tumor, the size of a lemon. The attacks of pain were paroxysmal, and on several occasions were almost followed by collapse. She had a vaginal discharge which contained shreds. Extra-uterine pregnancy was diagnosed. Abdominal section revealed a tubo-ovarian cyst the size of a lemon.

W. Gill Wylie[3] says that he has operated on three cases in which the diagnosis of extra-uterine pregnancy had been made, in two of which a supposed cure by electricity had been recorded, and at the operation no sign could be found of ectopic gestation having existed. The cases were simply those of Fallopian tubes dilated with fluid, one tube containing over two pints of fluid.

An article by Vander Veer[4] discloses two cases (Mundé and Janvrin) of pregnancy in one horn of a bicornate uterus, which were mistaken for ectopic gestation. He also reports two cases (Warren and Vander Veer) of normal pregnancy, mistaken for ectopic gestation.

It certainly is unnecessary to produce more evidence than this in order to convince the most sceptical that the symptoms of extra-uterine pregnancy are very often present when the disease is

[1] Annals of Gynecology, May, 1890.
[2] Personal communication.
[3] Annals of Gynecology, March, 1890.

[1] American Journal of Obstetrics, January, 1890.

[3] Ibid., January, 1890, p. 71.
[4] Ibid., November, 1889.

anything but an ectopic gestation. I am ready to grant that all the symptoms which we have considered as being produced by this disease were not present in each of the cases presented; but in what disease in the whole range of medicine are all the symptoms present in one case?

The most prominent and valuable points are noted in each case, viz.: the subjective signs of pregnancy, the pains, the missed menstrual period, and the bloody vaginal discharge containing shreds or masses, together with the cystic tumor in the region of the broad ligament. A study of these cases will show most decidedly that no other conclusion could have been arrived at in any single case, and in addition, the names of the attending physicians are a sufficient guarantee that the symptoms and history were carefully weighed. There are many more such cases on record, and very many which are not but should be.

It is interesting in connection with this to note the large number of diseases which have been mistaken for ectopic gestation in its early stages. Dr. T. Gaillard Thomas says: "There are few pelvic conditions which develop in the female, from phantom tumor to fæcal impaction, which I have not seen confounded with ectopic gestation." Amongst the few cases I have reproduced in this paper the mistake was made in cases of ovarian cyst, pyosalpinx, pelvic abscess, broad-ligament cyst, ovarian abscess, normal pregnancy, pregnancy in one horn of a bicornate uterus, and tubo-ovarian cyst. These are not all of the diseases which may be so mistaken. If the mistake is to be made in one class of cases oftener than another, I believe it will be in patients in whom an abortion has taken place, followed by a pelvic tumor (abscess or pyosalpinx)—or a pelvic mass may have existed formerly and unknown—the facts of the abortion being unknown or concealed. The case of Dr. Weeks, as quoted above, was such a one.

Now, with all these chances of mistake in diagnosis, have we considered all the possible errors? By no means. We still have to consider those cases in which extra-uterine pregnancy exists, but is not suspected, and cases in which it was taken into consideration, but was dismissed for lack of sufficient evidence. The following two cases which occurred in my own practice illustrate these points very well:

Case VI.—Mrs. R.[1] came to me complaining of abdominal and pelvic pain. After giving a negative history she was put on the table, a diagnosis of pyosalpinx was made, and an operation advised. One week later she sent for me, and I found her upon her bed. She said she had had abdominal pains during the entire week. She arose from her bed in order to obtain a letter. While on her feet she was seized with colicky pain. As I watched her the idea suddenly seized me that possibly this might be extra-uterine pregnancy. I carefully examined her with this possibility in view.

She had been bleeding, at times, for more than two weeks; the flow was pure blood, with no shreds or clot. She had not the slightest general or reflex signs of pregnancy; her husband had been away for only three weeks; she had not missed a period, nor had she had a scant one; and she had had children for the past six or eight years at regular intervals.

The examination showed the uterus in good position, and the cervix perfectly normal for a multipara. There was a mass posterior to and apparently continuous with the cervix, so that I had not been able clearly to feel the fundus anteriorly. I should have considered the mass the fundus. The only symptoms I had then for diagnosis were the bleeding and the pain. These symptoms are such constant and almost invariable companions of all serious pelvic troubles, that without something more to sustain the diagnosis it had manifestly to be given up. Dr. R. H. Hamill made a most careful examination for me, and could find nothing more on which to base a diagnosis; in fact, he did not think that it was a case of ectopic gestation. Our reasons for the diagnosis of pyosalpinx were the absence of symptoms of extra-uterine pregnancy, and the facts that the woman had been complaining of pelvic pain for the past three or four years, had pain at her menses, and painful coition and defæcation. She had had more or less leucorrhœa, which had suddenly become profuse, with itching about the vulva and painful micturition. She was in that condition of life in which one would expect her husband to infect her almost certainly with gonorrhœa. She had a high temperature and pulse, and chilly creeps. Taking it all in all, the indications were clearly for pelvic inflammatory trouble, and against extra-uterine pregnancy. It proved to be pregnancy of the fimbriated end of the tube.

Case VII.—Mrs. T. C.,[1] aged twenty-four years, married for nine years. Has had two children, and no miscarriages. The last pregnancy was six or seven years ago. After this labor she was in bed for eight weeks with a "sore and swollen belly," and since then she has never been free from pelvic and abdominal pain. Her menstruation has been regular but profuse, lasting eight or nine days. In the interim between her first illness (following the birth of her child) and the present, she had an attack of abdominal pain, which confined her to bed for a week or more. On November 15, 1889, she came to me stating that her regular menstrual period had come on five weeks previously, and that she had been bleeding more or less ever since. The constant pain she had been having had become worse. She had the appearance of a very sick woman, her temperature was elevated, her pulse quick, and she was having chills and creeps. An examination of the pelvis showed the uterus in fair position and of normal size. There were irregular cystic masses on each side, the larger being on the

[1] Medical Record, September 21, 1889.

[1] The Medical News, Feburary 15, 1890.

right. A diagnosis of chronic double pyosalpinx, with an acute attack of pelvic peritonitis, was made, and an operation advised. I removed from the right side a tubal pregnancy (verified by microscopical examination) which had advanced to about the sixth or seventh week; from the left side an ovarian cyst the size of a hen's egg.

The results of the operation were a complete surprise to me. My diagnosis of pyosalpinx, which was concurred in by Dr. T. Hewson Bradford, was made with the utmost confidence, and we had not the slightest doubt that it would prove to be correct. Ectopic gestation never entered into consideration. As soon as the patient was well enough I questioned her closely to see wherein we were at fault in our deductions. The questioning disclosed the following facts: At no time during the past year had she missed a menstrual period, nor had there been a scant or delayed one. At no time had she any signs of pregnancy, such as she suffered from when she was previously impregnated. In fact, she does not even now believe that she was pregnant, basing this scepticism on the absence of a missed period and the early signs of pregnancy. Her breasts were of normal size, the areolæ were not enlarged or changed in color; there was no tingling or itching about the breasts, though they contained a small quantity of milk—however, she states that such had been their condition since the birth of her last child. There was no decidual discharge: the only thing she passed besides blood was "a piece of whitish matter," such as she was in the habit of passing at the end of each menstrual period. This point has been most carefully inquired into, and she answers very intelligently. In addition to her statements we have those of a carefully-trained nurse. The patient was in the hospital two or three days before the operation, bleeding constantly. The nurse declares that the napkins were soiled with a discharge entirely free from clots or shreds. Stomach symptoms were entirely wanting. The pains were, according to her statement, not different from those she had with her previous attack of probable pelvic peritonitis.

In addition to these cases of my own, I will emphasize my position by reference to a few others occurring in competent and skilled hands.

G. M. Tuttle[1] reports the case of a woman who was under observation for several months. A diagnosis of double pyosalpinx was made. The operation revealed a pyosalpinx on the left side, with a tubal pregnancy on the right side.

H. T. Hanks[2] records a case on which he operated. The physician who sent him the patient said that she had suffered very little, and advised that no treatment be instituted. After reaching New York, however, she began to suffer, and a diagnosis of pyosalpinx was made. At the operation which followed a tubal pregnancy was removed.

[1] American Journal of Obstetrics, January, 1890.
[2] Ibid., January, 1890.

J. P. Tuttle[1] records a very interesting case. After carefully studying all the symptoms, he discussed the case at length with an experienced physician in New York, and after weighing the evidence *pro* and *con* they decided against ectopic gestation. The fœtus was afterward delivered through the rectum.

E. W. Cushing[2] mentions a case which had been operated on for an ill-defined tumor. The cyst was opened after the operation and a fœtus was found. There had not been a suspicion of pregnancy.

Smith[3] reports a case in which the patient died, and a post-mortem examination showed the right Fallopian tube distended into a sac, and containing a three months' embryo and placenta; the sac had ruptured, causing the death. He says, "In this case extra-uterine pregnancy was not suspected until I received the history of the symptoms immediately preceding death, nor can I see anything after reviewing the case which would have justified the diagnosis of tubal gestation. There was no attempt at abortion, no hæmorrhage, no pain referable to the uterus or tubes."

William T. Lusk[4] recently operated on two patients, and found extra-uterine pregnancy. In either case, under ordinary circumstances, it would have been impossible to make a diagnosis. He has in the last few years changed his views very considerably on this subject, and he now believes "that the number of cases in which we can diagnose extra-uterine pregnancy in advance is really very small."

Dr. Joseph Price in a recent discussion before the Philadelphia Obstetrical Society stated that he had failed to make a diagnosis in four out of the last five cases of ectopic gestation he had operated on.

I could quote many other similar cases, but I have already produced sufficient for my purpose.

It is here interesting to note the mixed character of the trouble in a number of the cases. My second case was complicated by an ovarian cyst on the opposite side. The case of Dr. G. M. Tuttle had pyosalpinx on the side opposite to the pregnancy. Cases have been reported where there was an ovarian cyst on the same side. Medical literature is full of such mixed conditions.

The class of cases we have been considering form no small proportion of the total number of cases of ectopic gestation on record, and in all human probability the vast majority of such cases are unrecorded. To give some idea of the immense proportion of mistakes which have been made in diagnosis during even the past few years, let us

[1] Annals of Gynecology, February, 1889.

[4] Journal of the American Medical Association, April 12, 1890.

compare some approximate figures. It is fair to assume that the total number of cases of extra-uterine pregnancy in its early stages which have been put on record in the United States during this period does not much exceed two hundred, if it reaches this point. At the end of the year 1888, Hanks[1] tells us that there were in the previous three years ninety-seven cases of extra-uterine pregnancies of all stages reported in all the journals published in the English language. It is also fair to assume that there were very few cases in this period of time which were diagnosed and not recorded. Add fifty cases to cover this possible discrepancy and we have an approximate total of two hundred and fifty cases diagnosed during this period of time. Now compare these figures with those of the other side of the story. With merely a superficial glance over only a part of the literature, I have found some twenty cases recorded (a few of which I have quoted above). It must be remembered that this does not by any means represent all the mistakes which have occurred, as men will conceal their blunders in spite of anything which can be said. In addition to these, which in themselves form a formidable percentage of the total number diagnosed (20 as against 250, or 12½ per cent.), I have the word of the coroner's physician of Philadelphia, Dr. H. F. Formad, that he has in his possession the specimens from more than thirty women who died from rupture of an ectopic gestation-sac (and I myself have seen and studied many of the specimens). These cases had been under the care of one or more physicians, and yet none had been diagnosed, and a post-mortem examination by the coroner's physician was necessary in order to ascertain the cause of death, it being supposed in many of the cases that they had been the victims of foul play. No reasonable man will contend that such cases occur only in Philadelphia, and if we make a calculation on a population of fifty millions or more we have an approximate total in the United States during the past few years of about 1500 deaths from undiagnosed extra-uterine pregnancy. Of course these figures are only approximate, and it would take a great deal of time to verify them. However, they are sufficiently accurate to give a thinking man plenty to reflect upon, and must carry conviction to the minds of most. Now, in addition, take into consideration all those cases in which the disease has existed, but was overlooked, and those, again, in which the diagnosis was made, and the disease did not exist, and our chances for a correct diagnosis fade to a minimum. I do not wish to be understood as thinking that it is always impossible to make a correct diagnosis in the early stages of extra-uterine pregnancy, because it has been accurately made, and I myself have made it, and verified the correctness of my diagnosis; the impression I wish to create is that in the great majority of cases the diagnosis can only be an approximate one, and when it is once made we are oftener likely to find ourselves mistaken than not. I think the evidence here produced more than sufficient to uphold that opinion.

THE USE OF ESSENTIAL OILS IN SURGERY.[1]

BY CARL E. BLACK, M.D.,
OF JACKSONVILLE, ILL.

SINCE the germ-theory of the cause of sepsis and infection became generally accepted, the minds of surgeons, experimenters, and money-makers have been actively engaged in seeking new and more efficient anti-septics and disinfectants. An antiseptic to meet the needs of many cases must fill several requirements.

1. It must fully inhibit the growth of or destroy microörganisms.

2. It must not be very irritating, and must not destroy the tissues.

3. It must be convenient to prepare and carry.

4. It must have a diversity of application.

The wider the "range of value" the more desirable is the antiseptic, and a non-poisoning antiseptic is more desirable than a poisonous one.

Further, antiseptics may be either stimulating or sedative to the tissues to which they are applied. This makes it necessary for us to have at least two antiseptics for everyday use. As a sedative antiseptic there is probably none better than carbolic acid, although there are several objections to it; namely, it is a poison, will destroy tissue, has a disagreeable odor, and considerable caution must be exercised in its employment. For general use, antiseptics which are stimulating without being irritating are more desirable; and for this purpose it seems probable that our best agents will be found among the essential oils.

For comparison we will refer to two or three antiseptics which are in common use. The following are the results of some experiments made by Dr. G. V. Black, with cultures of microörganisms submitted to the action of drugs in solutions of known strength for definite periods of time. Carbolic acid was found effective in the proportion of 1:300, or in the proportion of from 1:8 to 1:15 of a five-per-cent. solution. That is, one part of pure carbolic acid to three hundred of the culture-medium in which the microbes were growing, inhibited their growth; or one part of a five-per-cent solution of

[1] Read before the District Medical Society of Central Illinois, October 28, 1890.

carbolic acid to from eight to fifteen parts of the culture medium was equally effective.

A saturated solution of boric acid was found effective in the proportion of from 1 : 4 to 1 : 6.

Mercuric chloride was found effective in the proportion of from 1 : 25,000 to 1 : 50,000, or from 1 : 50 to 1 : 100 of a 1-to-500 solution.

Let us compare these figures with those obtained from similar experiments with the essential oils. Oil of cassia was found effective in the proportion of from 1 : 3000 to 1 : 5000, or from 1 : 2 to 1 : 8 of a saturated solution.

Oil of cinnamon was found effective in the proportion of 1 : 2000 or from 1 : 1 to 1 : 3 of a saturated solution.

Oil of cloves was found effective in the proportion of from 1 : 1100 to 1 : 1200, or in from 1 : 1 to 1 : 2 of a saturated solution.

Oil of mustard was found effective in the proportion of from 1 : 1000 to 1 : 1500, or from 1 : 1 to 1 : 2 of a saturated solution.

Oil of turpentine was found effective in the proportion of from 1 : 500 to 1 : 600, or in 1 : 1 of a saturated solution.

These experiments show mercuric chloride to be the most effective antiseptic, but its corrosive and poisonous qualities make it undesirable for general use. Both carbolic acid and boric acid are less effective than any of the essential oils named. Next in power to mercuric chloride is oil of cassia, made from the Chinese cassia bark. It is commonly sold as oil of cinnamon in our shops. One part of this oil to 4000 of the culture-medium was shown to be uniformly effective in inhibiting the growth of microbes. The Ceylon oil of cinnamon, made from the buds, is only about one-half as effective as that made from the Chinese bark. The other oils named are effective when used in larger proportions. One difficulty in the use of mercuric chloride is that it is not effective in the presence of albumin. All the albumin must be precipitated before the mercuric salt becomes active. Therefore in weak solutions its effects are uncertain, and in strong solutions its poisonous properties become dangerous.

The experiments with the essential oils were made about two years ago, and have recently been fully confirmed by the experiments of Dr. W. D. Miller, of Berlin, a member of the Imperial Board of Health of Germany.

It would consume too much time to give in detail the experiments, and the practical application of the results is more interesting. My experience has been almost exclusively confined to the oil of cassia, which was chosen because it was shown to be more effective and to have a wider "range of value" than any other of the oils, and in fact than any of the antiseptics in common use, excepting mercuric chloride. A review of a few of the cases in which I have used it will be of interest.

For more than a year I have relied on a solution of oil of cassia, the aqua cinnamomi of the Pharmacopœia, for cleansing the hands, instruments, patient, etc., in all obstetrical procedures, and always with good results. The same solution was used in all cases in which a wound was made, and primary union invariably followed. In cases of suppuration or necrosis the solution seems especially useful. In the case of a large cancer of the breast, involving the axilla, in which sloughing had extended to such an extent that the closed hand could be placed in the abscess cavity, the cassia solution soon diminished the suppuration and sloughing, and reduced the septic fever. In this case it was also efficient in relieving the disagreeable odor which accompanies the breaking down of carcinomatous tissue.

Another case was that of a man suffering from locomotor ataxia, who severely injured his foot. A few weeks later the bones of the second phalangeal articulation of the little toe were found necrosed. All the dead bone was scraped away and the wound cleansed with the solution of the oil of cassia. Healing promptly occurred, which, considering the general condition of the patient, was surprising. In a boy ten years old, who had had an abscess of the tibia for eight weeks, several sinuses were incised and the whole cavity thoroughly curetted, and dressed with the oil of cassia solution. The wound healed rapidly.

A rectal abscess was treated in the same way and with equally good results.

In a patient with necrosis of one and three-fourths inches of the outer plate of the body of the inferior maxilla, three sinuses were opened, the necrosed bone was scraped away, and the cavity washed with an emulsion of oil of cassia. In this case the entire wound healed at once and without further formation of pus.

In several cases of herpes circinatus the disease promptly disappeared after being thoroughly rubbed two or three times with the pure oil of cassia.

As an antiseptic wash in many forms of chronic nasal and pharyngeal inflammation the cassia solution gave excellent results, and at the same time was agreeable to the patient.

For a number of years dentists have used what is known as the "1, 2, 3" mixture, as an antiseptic for cleansing cavities and pulp-chambers, and for the treatment of alveolar abscesses. This mixture contains one part of carbolic acid crystals, two parts of oil of cassia, and three parts of oil of wintergreen. It seems in the light of recent experiments and experience, that the oil of cassia is the most active ingredient of the mixture, and that the

same results, so far as antisepsis is concerned, would be obtained if it was used alone.

A number of physicians and surgeons have used oil of cassia with results similar to those I have reported, so that the proof of its effectiveness is complete. The late Dr. David Prince chiefly relied upon the oil of cassia as an antiseptic, and used it in all his later abdominal operations.

The oil will inhibit the growth of or will destroy microörganisms. In solutions of effective strength it is not irritating, and will not destroy tissue. It has a "wide range of value," being exceeded only by mercuric chloride in the absence of albumin. It is not poisonous unless considerable quantities of the pure oil are used. The solution is convenient to prepare and carry, and has an agreeable odor. It has a considerable diversity of application.

An emulsion of oil of cassia causes some smarting at the juncture of the mucous membrane and skin, and irritates the tissues of the eye. The pure oil rubbed on the skin twice a day causes marked redness and a few blisters will appear about the third day.

The most common form in which oil of cassia or any of the essential oils is used is a watery solution, prepared by placing enough of the oil in distilled water to form a saturated solution, or by making the aqua cinnamomi of the Pharmacopœia.

The emulsion may be made by beating up the desired quantity of the oil in water. For local application it may be used in any strength for one or two applications, but is liable to cause irritation if applied frequently.

The oil may be mixed with powdered boric acid and applied as a dry dressing, or it may be made into an ointment with vaseline. In nasal diseases a favorite application is the oil of cassia dissolved in fluid cosmoline and applied by means of an atomizer.

It seems to me that no other antiseptic offers us so wide a range of adaptability with so few objections as the oil of cassia. In special cases some other antiseptic may be more desirable, but for general use this has many points in its favor.

MEDICAL PROGRESS.

Treatment of Keloid.—M. Vidal (*Annales de Dermatologie et de Syphilographie*) has observed that the cicatrices of scarifications made in keloids not only disappear rapidly, but that the keloid-tissue disappears with them. In recent growths one scarification may suffice, but the treatment of large growths must be continued for several months, and many patients are not willing to submit to the treatment for a sufficiently long time. If the treatment ceases when only a small nodule remains the growth will rapidly re-form; the scarifications must therefore be continued until the scar is everywhere soft and thin. The incisions should be made about one-fourth of an inch apart and "cross-hatched" either at right angles or obliquely, and should penetrate through the keloid, but must not extend for more than one-fourth of an inch beyond its borders. Previously to operating Vidal produces local anæsthesia by means of liquefied chloride of methyl, painting the surface with this until congelation causes the skin to whiten. As soon as the color begins to return the chloride of methyl is again applied, experience having shown that successive applications cause the anæsthesia to penetrate more deeply. The scarifications may usually be made to the depth of three-eighths of an inch without pain.

The loss of blood is not great and is immediately stopped by the application of absorbent wool saturated with boric acid solution. On the following day the surface is dressed with diluted mercurial ointment.—*Practitioner*, November, 1890.

Treatment of Ringworm of the Scalp.—According to the *St. Louis Medical and Surgical Journal*, Quinquand has devised the following method of treating ringworm of the scalp:

The hair is cut very short and the circular areas covered with scales and spores are scraped. The scraping induces a slight superficial dermatitis, and should be repeated at intervals of from five to eight days. During the intervals between the scraping the following solution is continuously applied:

R.—Biniodide of mercury	0.2	part.
Bichloride of mercury	1	"
Alcohol	4	parts.
Water	25	" —M.

On the fifth day after scraping, the following ointment is applied to the entire scalp in order to reach all new foci of the disease:

R.—Chrysarobin, Salicylic acid, Boric acid, of each	2	parts.
Vaseline	100	" —M.

After applying this ointment, the scalp is covered by a linen or rubber cap, held in place by means of Unna's zinc-glue. This is removed after forty-eight hours and the entire process is then repeated. In about a month epilation is practised and repeated, and the cure should be complete.

Errors in the Diagnosis of Infectious Diseases.—According to Russell, the following table derived from hospital statistics of Glasgow, shows the number of errors which have been made in regard to the diagnosis of contagious diseases:

Scarlet fever	508 cases	15 errors.
Measles	368 "	3 "
Whooping-cough	248 "	42 "
Typhoid fever	36 "	16 "
Typhus "	38 "	9 "
Diphtheria	64 "	2 "
Erysipelas	3 "	3 "
Puerperal fever	3 "	3 "

In other words there were 7.6 errors for each 100 cases, and prompt diagnosis, important in order that isolation might be practised for the prevention of the spread of disease, was in this number of cases wanting.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author.

Address the Editor: H. A. HARE, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including Postage.

PER ANNUM, IN ADVANCE . . . . . $4.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, DECEMBER 20, 1890.

LATEST INFORMATION CONCERNING KOCH'S DISCOVERY.

ASIDE from the abstract of the paper of Sir Joseph Lister, which we print as a special cable dispatch, in the EXTRA attached to this number of THE NEWS, we are glad to be able to give our readers other information from American investigations and foreign journals concerning the progress of this remarkable discovery. (See extra and page 670.)

It is very evident, as time goes on, that Dr. Koch has acted wisely in refusing to divulge the character of the anti-tubercular liquid, and it now appears that the criticisms which have been made concerning the secrecy of its preparation were exceedingly unjust to the great bacteriologist.

On November 7th, in other words a week before Koch's paper appeared, the distinguished investigator had a long discussion with the Prussian Minister, Herr von Gossler, in the presence of two witnesses, in which he stated that it was his desire to publish everything in connection with his research, including the method of preparation of the fluid. From the explanation which Koch gave to the Minister, it became evident to this official that a description of the preparation of the drug could only be followed by disastrous effects, if those who were not skilled in its manufacture should attempt to follow the directions given, for the method is so difficult in its details that it must either be seen or else be independently discovered by experiments, which, according to Koch's calculations, would take an experienced experimenter six months. For these reasons Herr von Gossler advised that this part of the discovery be kept a secret, and volunteered to take the responsibility of the information being withheld.

In his speech before the Prussian Diet von Gossler stated that in the present stage of organic chemistry the remedy cannot be analyzed with any degree of certainty, and that the method by which the remedy is obtained will probably render it applicable to other infectious diseases. He also stated that Koch himself lays special stress upon the chemical aspect of the subject.

The difficulties which exist in the manufacture of the remedy on a large scale are so great that the Prussian Government has been urged to put its authoritative stamp upon all of the liquid which was given out for experimentation in order to prevent fraud and to avoid the production of serious results by the use of impure material.

INFECTION FROM THE INTESTINAL CANAL.

IT is very generally believed that failure to procure healing *per primam* of tissues not previously infected can invariably be attributed to carelessness on the part of the surgeon or his assistants. This is doubtless a satisfactory rule of thumb, since it is in the great majority of cases strictly true, and since its tendency is to make more careful those in whose practice secondary local complications occur after operation. It should be recognized, however, that this rule has its exceptions, since dogmatic assertions to the contrary might not only cast undeserved reproach upon the most careful surgeons, but might even subject them to action at law to recover damages for a sequel to operation entirely beyond their control.

It is well known, for instance, that pathogenic microbes may gain access to the circulation by means other than those offered by the instruments of the operator, and may cause characteristic local effects in spite of rigid and successful antisepsis. Indeed, this has been so frequently observed in trauma not accompanied by surface-loss of continuity that the possibility of its occurrence in the operating-room must be admitted.

In addition to infection by the well-recognized

pyogenic microbes, it now seems probable that the bacterium coli commune may, exceptionally, play an important part in interfering with the healing of wounds. The possibility of wound-infection by microörganisms gaining access to the circulation by means of the intestines has long been maintained, especially by those interested in abdominal surgery. It is very generally admitted that in ulcerative conditions of the mucous membrane of the alimentary canal systemic infection may occur. But when the intestines are healthy, or subject to no greater alteration than that accompanying moderate catarrhal inflammation, proof has been wanting as to the possibility of harmful germs penetrating into the lymph- or blood-channels.

In this relation the communication of Tavel (*Correspondenzblatt für Schweizer Aerzt.*) is most important. He calls attention to a former paper in which he demonstrated the intestinal origin of two cases of acute goitrous inflammation. In both were discovered pure cultures of a gas-forming bacterium very similar to one found in the large intestines. The chain of evidence was incomplete, however, since he was not able to obtain the identical microörganism from the alvine evacuations.

Kocher many years ago expressed the opinion that inflammation in goitres was frequently secondary to an enteritis, but this has remained without positive proof till the present communication by Tavel. The chain of evidence in his last reported case seems complete. In January, 1890, Kocher operated upon a goitre containing two large cysts. One was enucleated—this was accompanied by much bleeding, checked only by sponge-packing; the other was enucleo-resected. The wound was drained, closed, and dressed with sublimate gauze. The following day the drainage-tube was removed. Gelatin into which portions of the tube were dropped remained sterile for several weeks; then a small colony of cocci, commonly found on tubes which have remained in contact with the skin, developed. These cocci were obtained from nearly all wounds which united by first intention. Healing took place rapidly. Eight days after operation, the wound having in the meantime completely closed, redness about the cicatrix and fluctuation were observed. Hæmatoma was suspected; an incision was made, and a brownish, bloody fluid, containing no clots, escaped. Microscopical examination was not made, but cultures showed an abundant growth of a short bacillus which proved to be the bacterium coli commune.

The cavity from which this liquid escaped was found to have grayish necrotic walls. No pus was discharged at any time. As healing was exceedingly slow, the curette was freely used. During this manipulation another cavity was opened and was found to contain a fragment of sponge. This cavity corresponded to the enucleated cyst. Small fragments of the portion of sponge showed that the latter was absolutely sterile. The proof that the bacillus observed in the completely-cicatrized wound was of intestinal origin would seem to rest upon the fact that the drainage-tube, when removed, was found to be practically sterile, that the piece of sponge removed from another portion of the field of operation was still sterile although it had remained in the tissues for a month; hence that infection had taken place after complete closure of the wound, consequently from within and not from without. A further indication of the origin of this infection rests upon the circumstance that nutritive enemata were required for a few days after the operation and that they had to be discontinued on account of a fœtid diarrhœa which seemed to be caused by them. On account of the very large loss of blood during the operation intravenous saline injections were practised in this case, and it might possibly be claimed that in this way the bacillus entered the circulation. The drainage-tube was not removed, however, for twelve hours after these injections had been made, hence had they been the direct cause of infection the presence of the bacterium would probably have been shown in the cultures from the drain.

Still another case of local infection of intestinal origin, though not following operation, is reported by Nicaise. In this case the patient suffered from a subacute cervical adenitis, which upon incision discharged a peculiar form of muco-pus. The author considers that the intestinal origin of this local trouble is exceedingly probable, from the fact that no cause could be found about the throat, head, or upper extremity, and that the patient was at the time suffering from a severe enteritis. It must be admitted that proof in this case is entirely wanting. It would also seem to be especially unlikely that, even were the general system affected, the local manifestation would appear in the neck.

Troisier, however, has shown that there exists some definite relation between the viscera and the cervical lymphatic glands, since enlargement of the latter is so common in cases of intra-abdominal

malignant disease that it is at times of diagnostic importance.

Whether or not the cases of local infection recently reported have really depended upon pathological conditions of the intestines, the fact remains that microbes can readily traverse intestinal walls which are in an abnormal condition. This would point to the very great importance of carefully attending to the condition of the alimentary canal, not only in abdominal surgery, but in all severe operations on any part of the body; and it would seem unwise to practise surgical intervention, save in cases of urgent necessity, upon those suffering from obvious intestinal disorders.

SPECIAL ARTICLE.

REPORT OF THREE CASES TREATED BY KOCH'S LYMPH.

BY WILLIAM H. BENNETT, M.D.,
OF PHILADELPHIA.

THE following records of cases treated with Koch lymph are, with one exception, incomplete, because the patients are still under treatment; and though they are of no value in indicating its curative effect, they are published at this time because of the great interest felt in every experiment made with the lymph.

The records will be completed in future numbers of THE MEDICAL NEWS, if the amount of lymph at my disposal proves sufficient. The specimen of it employed was obtained in such a way that it could not possibly have been diluted before reaching me, and it still retains its perfect transparency. It will, however, be seen that somewhat larger doses were required to produce the effects than those stated by Koch, and it is likely that the lymph slightly deteriorates either from age, or on its voyage across the Atlantic.

The first case well illustrates its value in diagnosis:

Mrs. C., a lady of seventy-nine years, weakened by age, a chronic intestinal catarrh, and a malignant disease of the face, was the first in Philadelphia to receive an injection.

The disease of the face had been pronounced lupus by a distinguished microscopist to whom had been submitted a portion of tissue removed last May. Although there was some doubt as to the correctness of this diagnosis, it was decided to test the question by an injection of the lymph.

The disease has existed for more than twelve years, but it has made very little progress until within the past eight months. During the latter period six operations have been performed by Professors Agnew and Ashhurst, with a view to check its inroads. It consists of an ulcer of irregular quadrilateral form, extending from a little to the right of the median line of the nose one and a half inches to the left, and from the lower edge of the nose nearly to the eyebrow. There is a hard, hemispherical nodule, half an inch in diameter, involving the inner half of the lower eyelid, and a similar smaller one on the inner edge of the upper lid. The flat surface of the hemisphere in each case forms part of the quadrilateral ulcer. The principal activity of the disease is in these nodules. The floor of the ulcer is covered with granulations showing no tendency to cicatrize. The right-hand border has on it a few warty papillæ, and from it extend, here and there, into the sound tissue, grayish lines, indicative of the invasion of the disease into other regions.

At 5.30 P.M., December 10, 1890, in the presence of Professors Agnew and Ashhurst, I injected between the shoulder-blades 0.002 c.cm. of lymph which had just been diluted with boiled distilled water. There was only the ordinary pain of a hypodermic injection. The following is a record of the pulse and temperature:

Time.	Pulse.	Temperature
P. M.		
5.45	80	98.4°
6.15	76	98.4
6.45	76	98.4
7.15	75	97.
7.45	72	97.6
8.15	74	97.6
8.45	78	97.6
9.15	—	97.6
9.45	—	97.6
10.45	—	97.8
11.45	78	97.8
A. M.		
2.15	—	97.8
8.45	91	98.4

There has not been at any time a change in the appearance of the ulcer, except that, in consequence of the removal of all dressing and exposure to air, it becomes dryer and darker. The site of the injection could not be discovered at 6.45 P. M. It had become slightly red and tender by 8.45 A. M., December 11th. The patient at that time seemed in better condition than before the injection.

At 9.30 A. M., December 11th, a second injection was given, consisting of 0.005 of lymph. The following is the record of pulse and temperature:

Time	Pulse.	Temperature.
A. M.		
10.00	80	98.4°
10.30	87	99
11.00	87	99.1
11.30	87	98.4
12.00	84	98.8
P. M.		
1.00	76	98
2.00	94	99
3.00	100	98.8
5.30	90	99
9.00	94	99.4
10.00	93	100
12.00	79	99.6
A. M.		
9.00	91	99.6

By 2 P. M., December 11th, the site of the first injection had become quite red over an area of one and a half inches in diameter, and two lymphatic glands near the shoulder were enlarged and tender. The second injection produced some disturbance of the system, shown by a rise of temperature to 100° and a general feeling of malaise. The ulcer was in no way affected, and there were no other symptoms worthy of note.

A third injection of 0.01 c.cm. of the lymph, freshly diluted, was given at 12.30 P. M., December 13th, the temperature at that time being normal. The following record was made:

	Time.	Pulse.	Temperature.
	P. M.		
Dec. 12th.	1.30	88	99 °
	2.30	89	99 2
	3.30	91	99.2
	4.45	82	99 4
	6 00	83	99.2
	8.15	93	99.4
	10.00	91	98.3
	A M		
Dec. 13th.	9.00	90	99.4

The effect of this injection upon the system was hardly appreciable, and again the sore showed no change.

The following note was made of the condition of the sites of the injections, December 13th:

No. 1. The redness is fading, and the enlarged glands are growing smaller and less painful.

Nos. 2 and 3 are each slightly red and tender, but no more glands have become enlarged.

December 15th, at noon, a fourth injection was given of 0.02 c cm. of lymph—a large amount for so feeble a person. The following record was made of the result:

	Time.	Pulse	Temperature.	Notes
	P. M.			
	1.00	72	94.8°	
	2.00	77	98 4	
	3.00	77	98.4	
	4.00	90	98.8	
	5.00	91	99	
	6.00	100	100	Slight chill.
	6.30	112	100.8	
	7.10	123	101	
	7.40	110	102	
	8.15	106	102	
	8.45	110	102	
	9.15	110	102 2	
	9.45	105	102.2	
	10.30	110	102.2	
	11.00	110	101.4	
	12.00	113	102	
	A. M.			
Dec. 16th.	1.00	107	102	
	2.00	100	100	
	10.00	97	98.8	

It will be seen by the above record that there was at this time a decided reaction. The patient complained at 1 P.M., one hour after the injection, of a sudden momentary buzzing in the ears and a feeling as if about to faint. With the slight chill there was a sensation of pulsation in the back of the head and shoulders. At 7.30 P.M. the respiration became somewhat irregular, and there was a constant effort to clear the throat by coughing. There was at no time actual nausea, but she was "afraid to eat lest it should come on." Between nine and ten she became for a time very restless, and complained of pains in the limbs. She passed an uncomfortable night, having but little sleep. December 16th, she felt better, but weak. The wound did not change at all in appearance, and since the first injection the disease has apparently spread with at least as great rapidity as ever before. It is evidently not lupus.

The second patient treated was a woman of twenty years, suffering from tuberculosis of the lungs. The case is one of a year's duration, with a typical history of heredity, cough, hæmoptysis, hectic, and loss of flesh. A moderate-sized cavity exists in the apex of the left lung, and the sputa are loaded with tubercle bacilli.

December 12th, at 3.10 P.M., I injected between the shoulder-blades 0.005 c.cm. of Koch's lymph. The following is the record made of the pulse, respiration, and temperature:

Time.	Pulse.	Temperature.	Respiration.
P.M			
3.10	134	99.8°	25
3.30	126	101.4	24
4.00	126	101.2	29
4.30	122	101.1	30
5.00	120	101.1	28
5.30	114	101.1	28
6.00	120	101.1	26
6 30	126	101 2	26
7.00	124	101.3	26
8.00	120	101.2	25
9.00	120	101.0	24
10.00	118	100.8	24

No record could be taken after 10 P.M., but the patient continued feverish until 3 A.M. In this case there was no decided chill. With the fever there was for a short time slight delirium. The cough was increased, and became very troublesome during the night. There was some nausea. There were pains throughout the body, but especially in the arms and legs, which continued with gradually-decreasing intensity for twenty-four hours. There was no perceptible effect upon the bowels, skin, or kidneys. The morning after the injection the appetite was as good as usual, and with the exception of increased weakness and the lingering pains, the patient was in no way the worse for the injection. The reaction in this instance was characteristic but slight, most of the rise of temperature being due to the daily hectic.

December 14th, at 2.20 P.M., I gave the patient a second injection, consisting of 0.01 c.cm. of lymph, with the following result:

Time.	Pulse.	Temperature.	Respiration.
P M			
3 00	120	100.8°	24
3.30	116	100.8	30
4.00	118	100.4	26
4.30	120	100.6	28
5.00	120	100.2	24

Time.	Pulse.	Temperature.	Respiration.
P.M.			
5.30	115	100.2°	28
6.00	114	100	28
6.30	118	100	30
7 00	120	100	30
7.30	120	100 8	30
8.00	112	101.4	26
8.30	120	102.5	28
9 00	130	104	28
9 30	135	105.2	26
10 00	135	104.8	30
10 30	112	105	28
11.00	108	105.1	28

There was nothing of importance to note until seven o'clock, when the patient vomited a little mucus slightly tinged with blood. At 8 P.M. the cough was increased, but was accompanied with very little expectoration. At 8.30 P.M. she complained of slight chilliness of the body, and the hands, which were previously warm, became cool. At 9 they were cold, and the patient still complained of chilliness of the body. At 9.30 this latter sensation had passed away, but the hands were still cool. During a hard coughing spell a little mucus was raised, which contained no blood. A slight pain, lasting a minute or two, was felt in the left chest on rising. At 10 P.M. there was slight pain in the lower part of the back and in the back of the thighs. The patient became somewhat delirious. The cough decreased. At 10.30 there was slight supra-orbital and occipital pain. After 11 P.M. no record could be taken, but the fever gradually abated toward morning, and the next day, December 15th, the patient complained only of weakness. At 2.30 P.M. her pulse was 120, and temperature 99.8°. The following note was made on December 16th: "Since the last injection the patient feels better, and her cough and expectoration are decidedly diminished."

Arrangements will be made for more injections during the ensuing week.

The third case which I have to report is that of a boy five years of age, who was admitted to St. Christopher's Hospital for Children nine months ago with incipient disease of the left hip-joint. His mother died of tuberculosis of the lungs and his sister of Pott's disease.

A periarthritic abscess formed during the past fall, which was opened November 8th by Dr. Simes, the attending surgeon. After discharging freely for three weeks it remained closed for one week, and then about a week ago commenced to discharge again.

At 4 P. M., December 13th, in the presence of Dr. D. D. Stewart and myself, Dr. Simes injected, in the usual place, 0.005 of Koch's lymph. The following record was made of his temperature and pulse.

Time.	Pulse	Temperature.
P M		
4 00	88	98.8°
4.30	112	99.2
5 00	104	99.3
5.30	100	98.8
6.00	92	98.4
6 30	92	98.4
7.00	100	98.2°
7.30	104	98.
8.00	99	98.4
8.30	92	98.4
9 00	100	98.4
9.30	108	98.6
10.00	114	98.8
11.00	116	100.
A.M.		
6 00	130	102.
7.00	130	102.
8.00	144	102.4
9.00	140	102.
10.00	130	102.
11.00	144	102.
12.00	132	101.8
P.M.		
12.30	140	101.6
1.30	136	
3.30	144	101.6
4.30	132	101.9
5.30	132	101.8
6.30	124	
8.00	112	101.6
10.00	116	101.6
A.M.		
6.30	112	99.

The injection was followed very quickly by a slight flushing of the face and an irregularity of the pulse. This irregularity of the pulse was a marked symptom during the whole period of high temperature, and it was also quite marked when, at 6 P.M., the temperature was normal. It disappeared as the child recovered from the injection. The child is free from heart trouble.

There were no other symptoms to note until 9.30 P.M. The child then complained of stiffness and a "sore feeling" in the diseased joint, but not of any pain in the right leg. At ten the joint was slightly swollen and inflamed. At eleven there was a well-marked red ring half an inch broad around the opening of the abscess. Later, the redness extended over the joint, and it became so sensitive that the child feared to have any one touch it. The discharge was slightly tinged with blood. The temperature was not taken during the night, but the child was very restless and feverish, constantly asking for water. At 6.30 the following day he vomited. During that forenoon his face was slightly flushed, his eyes injected, and he complained of headache. He slept much of the time, keeping his eyes partly open. His appetite had failed, his tongue had a brownish coat in the centre and was a strawberry-red along the edges. The urine contained no albumin; it was very turbid on the day following the injection, but quite clear the next day. December 15th, the child was still pale, but he had regained much of his usual animation. The red ring around the opening had become very narrow, and the heat about the joint and its unusual sensitiveness had disappeared.

This case is one of special interest, and further injections will be made and reported as soon as

arrangements can be made for continuous and more careful observations.

It will be seen that the symptoms in the foregoing cases corresponded with those described by Koch as developing under similar circumstances, but how far the treatment in the last two will prove curative can only be determined by further injections.

I am indebted to Drs. McCamy and Lawrence, and to medical students Bennett, Woodward, and Van Dyke, for assistance in making the foregoing records.

INOCULATION OF KOCH'S LYMPH AT THE HOSPITAL FOR THE RUPTURED AND CRIPPLED, NEW YORK.[1]

Preliminary Report.

By ALLAN McLANE HAMILTON, M.D.,
NEUROLOGIST,

AND

VIRGIL P. GIBNEY, M.D.,
SURGEON-IN-CHIEF.

Remarks by Dr. Gibney.—On Tuesday morning, December 9th, Dr. Hamilton notified me that he had a small vial of Koch's lymph and would like to employ it in a case of tubercular meningitis. I replied at once that we unfortunately had no such case at present in hospital, but had any number of cases of bone tuberculosis, and would be glad to have him call in the afternoon to make such experiments as he desired.

Case I.—At 5.30 P.M., in the presence of two members of the consulting staff, Drs. J. H. Ripley and L. E. Holt, Dr. W. R. Townsend, Assistant Surgeon, Dr. George DeF. Smith, and the members of the house staff, the first inoculation in a public institution in this city was made upon a boy, ten years of age, who had been under treatment in the hospital for several years for tubercular osteitis of the right hip. This case was selected because his general health was good, because the sinuses had closed, and because it was believed that a cure was complete. Dr. Ripley examined his lungs with negative results. His pulse was 76, respiration 20, and temperature 98⅘°. The syringe had been previously sterilized and 2 minims of the solution, of the strength of 1 mgm. to 5 minims, were injected in the interscapular space by Dr. Hamilton. At 6.45 P.M. his pulse was 80, respiration 20, temperature 98⅗°. At 7.45 P.M. pulse 76, respiration 20, temperature 98½°. At 8.45 and 9.45 the vital signs were practically the same. At 10.45 his pulse was 72, respiration 19, and temperature 99°. There was no rise of temperature beyond this. He slept well during the night and kept his bed during the following day, Wednesday. He complained of a little soreness about the puncture and there was a slight area of redness, but beyond this there was nothing that could be construed as reaction. At 6 P.M., December 10th, 5 minims of the same solution were injected, and up to the present writing there has been no reaction.

Case II.—A member of the house staff was selected as a healthy subject, lungs examined by Dr. Ripley with negative result, and 5 minims were injected in the interscapular space. Careful records were kept during the evening without any positive result. In the morning the doctor reported that he experienced no change whatever, save a little accentuation of pain around some scratches on his hands, produced by plaster work.

Case III.—December 10th, boy, aged twelve years, typically tuberculous in appearance, in hospital since May, 1889. Excision of the knee for tubercular disease had been performed last spring. A large portion of bone had been removed, but sinuses remained and these had been treated with the peroxide of hydrogen. In addition to the sinuses, an ulcer, supposed to be tuberculous, existed on the posterior aspect of the thigh. This case also was selected in the hope that the process had been arrested. Dr. John S. Thatcher examined his lungs with negative results. Injection of 5 minims at 6.20. A careful record was made every hour preceding and subsequent to the inoculation, from 5 P.M. to 12 midnight. There was no elevation of temperature whatever. This morning, December 11th, the boy reports himself as feeling quite well; complained during the night of pain in his back, which pain prevented him from sleeping; beyond this, no reaction.

Case IV.—December 10th, girl, seven years of age; under treatment since May 23, 1890, for dorsal Pott's disease with an abscess about the right hip. This had been opened and treated after Billroth's method. For the past week she has been out of health, had a decidedly "strumous" appearance, and, for the past day or two, has suffered from a phlyctenular conjunctivitis. Her lips were large and flabby and eyes heavy. Dr. Thatcher examined the lungs, pronouncing them healthy. At 6.25 P.M. 3 minims of the same solution were injected, the usual records having been made. At 11 o'clock in the evening, the night nurse reported that the child was suffering from "snuffles," was breathing heavily, and was not resting well. The vital signs, however, showed no change. This morning, December 11th, she is resting comfortably, her vital signs are normal, and she does not complain of any pain about the site of puncture.

Report of Dr. Allan McLane Hamilton

To the Editor of The Medical News.

Sir: On Monday, December 8, 1890, I received from Dr. H. Holbrook Curtis, of this city, about four grammes of diluted Koch's lymph, every five minims of which contained one milligramme of the lymph. The attenuation was made on the previous day with sterilized water, by Dr. Curtis himself. Through an unfortunate accident one-half of this solution was lost upon the afternoon of Tuesday the

[1] This report was received from Dr. Hamilton on Friday, December 12th, too late for insertion in the issue of The Medical News for December 13th

9th, when I made my first two injections, at the Hospital for Ruptured and Crippled, in the presence of Drs. Gibney, Townsend. J. H. Ripley. L. Emmet Holt, George DeForest Smith, and the house staff. Two more patients were injected on Wednesday. in the presence of several of these gentlemen. as well as Dr. Thatcher. These cases are fully reported elsewhere,[1] and I will not refer to them except to say that the reactions were either absent or trifling. and that one of the cases was non-tuberculous and another convalescing. From the fact that other medical men have had decided results with Koch's lymph injected by them, and that Dr. Curtis himself has materially influenced the course of the disease by injections of the same lymph used by me, I am compelled to believe that the barren results from its use in my hands were due either to the smallness of the do-e used (2 mgm. to 5 mgm.) or possibly to the fact that the diluted lymph had undergone decomposition. I, however, hope to make other injections toward the end of the week, employing the same patients; when I will forward you my further experiences.

Very truly yours,

Allan McLane Hamilton, M.D.

New York, December 15, 1890

CORRESPONDENCE.

CHICAGO.

To the Editor of The Medical News,

Sir: A new specialty in medicine has apparently been created in Chicago. A certain so-called doctor advertises himself as "the successful obesity specialist; patients treated by mail; no starving, no inconvenience; harmless, and no bad effects." We are informed that this man has a lucrative practice, and that as might be supposed a large proportion of his patients are Germans.

At a recent clinic at the College of Physicians and Surgeons Professor A. Reeves Jackson showed a case of laceration of the cervix, and in commenting upon these injuries said that their pathological importance frequently, though not always, depends upon the degree of eversion which accompanies them. In this case there was no eversion unless the parts were pulled upon and thus separated. The "out-rolling" of the cervical lining is most marked in cases in which the laceration is bilateral, and extends beyond what might be called the crown of the cervix. In such cases it is not unusual to find the internal os at the very lowest portion of the everted tissues. These extreme cases can be cured by plastic operations only. Dr. Jackson regards all cervical lacerations as inviting the development of malignant disease, and when a woman has a cervical tear and is approaching the menopause she should be taught to watch carefully for such symptoms as hæmorrhage, leucorrhœa, or pelvic pain, for any of these may signify incipient cancer and indicate the necessity for prompt treatment.

Professor Jackson then put the question, "What should be done in the way of treatment in this case?" and added that when Emmet taught us the frequency of this lesion, and the admirable method by which the injury might be repaired, and its effects consequently removed, almost the entire profession agreed with him. Every physician who could do so operated upon every torn cervix when permission could be obtained. But a change has come. The pendulum swung too far in one direction and it is now likely to swing too far in the other. Dr. Jackson believes that the operation is needed particularly in cases in which there is great eversion. We can in some cases effect a cure by local treatment, but even in these if by a procedure of from fifteen to thirty minutes we can in one or two weeks accomplish what would otherwise require many months, the operation should be done. In the case before the class he did not think that an operation would be necessary, and he therefore applied Churchill's tincture of iodine to the interior of the cervix and to the eroded surfaces. This, or carbolic acid, or the two combined, should be applied to the unhealed surface once a week. Between the applications the cervix should be sustained by a vaginal tampon of absorbent wool or cotton, saturated with boric acid and glycerin, and changed every two days. If, however, at the end of a month's treatment, and after involution is complete, the condition is not improved, an operation should be performed.

Dr. G. Frank Lydston recently had an interesting case of non-gonorrhœal double epididymitis. Double epididymitis, as is well known, is rare, and double epididymitis of non-gonorrhœal origin is especially rare.

The patient gave a history of a slight stricture following an attack of gonorrhœa six years ago. This was treated successfully, but since then he has been subject to prostatic irritation, and occasionally suffered from urinary obstruction apparently due to spasmodic stricture. He stated that he had been examined by several surgeons who informed him that his stricture was very slight, but that the prostate was exquisitely tender, a fact which he himself keenly realized when a bougie was introduced. Since the original gonorrhœa there has been no discharge whatever. The patient had been subject to slight muscular rheumatism, and four days before coming under Dr. Lydston's observation he was attacked by what was apparently severe lumbago. On the second day of this attack the right testicle became painful and swollen. On the third day the inflammation of the right testicle subsided somewhat and the left became enormously swollen and acutely painful. Under appropriate treatment the swelling of the left testicle subsided within forty-eight hours, and on the following morning the patient was very comfortable. In the evening, however, the right testicle again became swollen, and it was necessary to give opiates quite freely in order to relieve the pain. The peculiar feature of the case is the fact that a decided decrease followed by a rapid increase in the size of the inflamed organs occasionally occurs within a very few hours. The body of each testicle has become secondarily inflamed.

Dr. Lydston believes the case to be one of rheumatic orchitis and epididymitis, but that there is in all proba-

[1] See page 673 this issue.

bility some predisposing cause in the deep urethra. He thinks that rheumatic inflammation of the testicle is much more frequent than is generally believed.

Dr. T. Melville Hardie recently contributed a paper to the Chicago Medical Society on the "Local Treatment of Laryngeal Tuberculosis." The paper was largely a review of the work done in laryngeal tuberculosis by Heryng, of Warsaw, and Krause, of Berlin. The frequency of laryngeal involvement in pulmonary consumption, the existence of primary laryngeal tuberculosis, and the occurrence of frequent cicatrization under treatment were adduced as reasons for departing from the customary therapeutic nihilism. Case-histories were read which showed that at least a partial cure is possible, and that the troublesome subjective symptoms, dysphagia, difficulty in breathing, and hoarseness, can be removed or greatly alleviated. The points requiring attention in the lactic-acid treatment were mentioned and a discussion of the rationale and of the surgical methods employed in the treatment of laryngeal tuberculosis followed. It was insisted upon that the introduction of *curettement* marked an epoch in the treatment of the disease, as it is based upon the conclusions arrived at by modern general surgery with regard to the treatment of tubercular joints. The technical difficulties in the way of the effective accomplishment are not to be urged to its discredit. It is not work for a beginner. Besides *curettement* and treatment by endolaryngeal incision, tracheotomy and electrolysis were briefly discussed. The writer had had no experience with electrolysis.

LONDON.

The Medical Schools—The London Post-graduate Course—Dr. Sharkey on Graefe's Lid-sign—Fatal Obstruction of a Bronchus in an Infant.

THE number of new men in the London medical schools is almost exactly the same as that of last year, but less than that of the preceding two or three years; but those of us who think the profession is already overcrowded will not find any cause for regret in this fact. Of course, St. Bartholomew's Hospital takes the lead, as it has for many years past, and Guy's has resumed its old place as next to the largest school, a position which has been stoutly contested by St. Thomas's in recent years. The new dental school at Guy's is becoming known, and this year quite a number of "dentals" have entered there, but without affecting the number that enter elsewhere; so I suppose the dental profession also will become overcrowded.

I hear, on good authority, that the London post-graduate course is in a flourishing state, and that the number of names enrolled for the third and concluding series of lectures and demonstrations is equal to that of the two previous series together. This would seem to show that the medical public is awakening to the great advantages which the course offers. I am told that the Government departments are looking upon it with favor, and granting leave of absence to officers in the army and navy who wish to "brush up" by attending the course. Several naval officers have entered, and there are rumors of a considerable accession of numbers from the same quarter in the course of a few weeks. For some reason, I suppose because it is not yet sufficiently widely known, but very few foreign practitioners have joined, three Canadians and one American representing the total of those who do not hail from the British Isles. An editorial in your journal, August 30th, on the subject of the advantages presented by London as a medical centre was read here with much interest and approval, and probably its effects will soon be shown by the number of men who will stop here instead of hurrying on to Vienna or Berlin.

Dr. Sharkey recently read an interesting paper on Graefe's "lid-sign" before the Ophthalmological Society. This sign consists, as is well known, in the non-descent, or, rather, the imperfect descent, of the upper eyelid when a patient suffering from Graves's disease looks downward. That it is not a constant symptom every physician will admit, but Dr. Sharkey has gone further than this, and shows that it is present in a not inconsiderable number of persons who are not the subjects of Graves's disease at all, and that, therefore, it has not the pathognomonic significance which has hitherto been accorded to it. His reasoning on the cause of the phenomenon was so good that I need make no apology for quoting it: "It is clear," he said, "that there is overaction of the muscles which raise the lid, namely, the levator palpebræ, supplied by the third nerve, and the unstriped muscle of the lid, supplied by the sympathetic. Remak showed that irritation of the sympathetic produced elevation and retraction of the upper lid; and the fact that one can voluntarily produce this, shows that it can likewise be effected through the third nerve. Constant active spasm rarely results from irritation, though intermittent spasm may. Prolonged spasm most frequently owes its origin to paralysis or weakening of opposing muscles. Is there evidence in Graves's disease of a weakening of the muscles which close the eyes? Stellwag has shown that a very constant symptom of the disease is diminished frequency and incompleteness of the involuntary closure of the eyes, which goes on so continuously in health. The orbicularis palpebrarum which effects this movement and is the opponent of the muscles which raise the lid, being weakened in Graves's disease and losing tone by inaction, the healthy equilibrium of the muscles of the eye is lost, the opening overpowering the closing muscles and producing retraction of the upper lid and Graefe's sign. Thus the infrequency of winking, which Stellwag refers to disease of the nerve-centres, is the primary result of disease, and retraction of the lids and Graefe's sign follow as a consequence."

At the first meeting of the Clinical Society, Mr. R. W. Parker reported a very interesting case and a somewhat unusual form of disease. His patient was an infant, one year old, who was suddenly seized with very urgent dyspnœa, and as the obstruction to respiration was evidently below the larynx, she was naturally assumed to have aspirated a foreign body into the air-passages. Tracheotomy was performed and efforts were made to promote the expulsion of the foreign body, but without success, and the infant died soon afterward. On post-mortem examination it was found that the entrance to one bronchus was completely occluded by a caseous gland, which

had ulcerated through the trachea and sloughed into the trachea. Of course, it is common for caseous glands to become adherent to the trachea, and they not infrequently lead to ulceration; but when perforation has been accomplished the contents of the gland are generally poured into the trachea in a fluid state, and set up a gangrenous pneumonia. The sloughing of the whole gland, such as took place in this case, must be very rare, and the extremely early age at which it occurred is also another point of interest.

Dr. Andrew, the Harveian Orator of the College of Physicians this year, in the course of this address, spoke of the enormous amount of so-called medical literature as the chief of the ills which beset the physician of the present day, and said that this evil would be less prominent if writers paid more attention to the teachings of Harvey, from whom he quoted the following passage in support of his belief: "I had no purpose to swell this treatise into a large volume by quoting the names and writings of anatomists, or to make a parade of the strength of my memory, of the extent of my reading, and of the amount of my pains; because I profess both to learn and teach anatomy, not from books, but from dissections; not from the positions of philosophers, but from the fabric of Nature. I avow myself the partisan of truth alone; and I can, indeed, say that I have used all my endeavors and bestowed all my pains on an attempt to produce something that should be agreeable to the good, profitable to the learned, and useful to letters." It would, indeed, be well if all writers since his day had laid Harvey's precepts to heart and endeavored to act upon them.

NEWS ITEMS.

Opinions of Foreign Journals.—The following excellent summary of the opinions expressed by French and German journals as to Koch's treatment of tuberculosis is taken from the London *Lancet*, December 6, 1890:

In France the reception of Professor Koch's discovery by the medical press has been fairly cordial. Some journals, as the *Gazette Médicale de Paris* and the *Progrès Médical*, are content with giving abstracts of the recently-published reports from Berlin, the last-named expressing surprise at the moderate and somewhat vague terms in which the action of the remedy is now being spoken of, compared with the more enthusiastic language first used. *L'Union Médicale* (November 27th, 29th, and December 2d) has followed carefully the progress of events. It points out that more caution is being used in the employment of the remedy, especially in view of its liability to induce acute pulmonary œdema in lung tuberculosis, or œdema of the brain in meningeal cases, or of the glottis in laryngeal disease. Surgical cases are more amenable to treatment because of the readiness with which the diseased parts can be completely extirpated after the remedy has exerted its necrotizing effect. It refers to von Ziemssen's opinion that lung cases will require prolonged treatment. M. Villoret, writing from Berlin to the *Semaine Médicale*, insists on there being a certain idiosyncrasy in the manner in which the injections are borne, and cites three cases treated by the same dose, in one of which a typical reaction took place after fifteen hours, in the second an "atypical" one after three hours, and in the third a weak but typical reaction after ten hours. *L'Union Médicale* thinks that we are still much in the dark, and points to the fact that relapses have already occurred in lupus-cases and that it is an error to believe that we are at all near proofs of its real therapeutic efficacy. At the Laennec Hospital on November 30th, MM. Cornil and Chantemesse inoculated six patients—two being cases of lupus, two of early pulmonary tuberculosis, and two of surgical tubercular affections. In one of the lupus-cases, a man of eighteen years, 0.002 c.cm. was injected, and reaction began five hours after, the temperature reaching its maximum in twelve hours (39.2° C. from 37.2°). The appearances were precisely similar to those described by all who have tried the remedy in lupus.

There was equally marked reaction (maximum temperature 39.4° C.) in a case of early phthisis, with headache and nausea, and slight auscultatory changes attributed to congestion. M. Pean on the 29th inoculated several cases at the St. Louis Hospital. He expressed the opinion that Koch was justified in withholding the nature of the remedy at present, and insisted on the danger of incautious administration. Dr. Moreau, of Algiers, asserts that in some well-marked tubercular cases no reaction has followed injection, and that in some non-tubercular subjects reaction has been observed. In one case of Leyden's the fever set up by the injections continued after these were discontinued. *La Province Médicale* (Nov. 29th) thinks that enthusiasm is giving way to uncertainty, and avers that in pulmonary cases its action is very limited, and that, although it may cause diminution in expectoration of bacilli and in night-sweats, its use is not followed by any gain in weight or strength. Much is required to be known concerning the length of time that such cases have to be treated. The *Gazette des Hôpitaux de Toulouse* defends Koch for his reticence, since he was forced to publish his results prematurely. It says that in showing that the "lymph" has an elective affinity for tubercular tissue, his researches are to be greatly praised. It raises the question as to the desirability of "curing" the phthisical. The *Allg. Wiener med. Zeitung* (Nov. 25th) devotes much space to contributions on the subject, including one by Dr. Buchner, of Munich, who points out that inflammatory action may play the chief part in the destructive process. The *St. Petersburger med. Wochenschr.*, November 17th, states that on November 11th Professor Anrep gave an address on the subject, and inoculated three lupus-cases with some of the "lymph" given him by Professor Koch. Other delegates have also gone to Berlin, and many physicians from all parts of Russia. The remedy has also been used in Professor Baccelli's clinic at Rome.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING DECEMBER 13, 1890.

Bloodgood, Delavau, *Medical Director.*—Ordered to Charleston, S. C., to represent the Medical Corps of the U. S. Navy at the meeting of the American Public Health Association.

Ames, H. E., *Passed Assistant Surgeon.*—Ordered as delegate to Charleston, S. C.

Bertolette, D. N., *Surgeon.*—Detached from the Naval Hospital, Philadelphia, and ordered to special duty in connection with the World's Columbian Exposition.

Dickson, S. H., *Passed Assistant Surgeon.*—Detached from the "Atlanta," and granted two months' leave of absence.

Wentworth, A. R., *Passed Assistant Surgeon.*—Ordered to the U. S. S. "Atlanta."

ORIGINAL ARTICLES.

AN INVESTIGATION INTO THE ETIOLOGY AND TREATMENT OF PHTHISIS.

BY HENEAGE GIBBES, M.D.,
PROFESSOR OF PATHOLOGY IN THE UNIVERSITY OF MICHIGAN,

AND

E. L. SHURLY, M.D.,
PROFESSOR OF LARYNGOLOGY AND CLINICAL MEDICINE IN THE DETROIT COLLEGE OF MEDICINE.

IN a series of papers published by us in the *American Journal of the Medical Sciences* we endeavored to show from the experiments and investigations of many observers, together with our own, that tuberculosis and phthisis pulmonalis are different disease-processes—resting we believe upon distinct pathological and clinical bases. Our therapeutic experiments looking to the discovery of some one agent to act as a specific against these conditions have only confirmed us in the belief. While we have demonstrated to our satisfaction that attenuated cultures will prevent the development of general tuberculosis in guinea-pigs, we have found that such cultures will not in any way prove curative when the disease has started. We have therefore been aiming to discover some agent or agents which will prevent further development in the diseased organ, or organs, and also neutralize in the economy the ptomaïnes circulating at large.

Owing to the various changes which chemicals are apt to undergo in the stomach and intestines before final diffusion, it is obvious that hypodermic medication offers, perhaps, the only rational and accurate method of arriving at desirable results; while the introduction with the inspired air of an agent which will modify and arrest the local process, when situated in the lungs, will most likely assist in cutting off the supply of septic material generated and diffused, as well as prevent further development of disease in the locality.

We have been experimenting continuously for more than two years with a great variety of agents, often with most discouraging results. Of all the agents for inhalation which we have used, we find that chlorine gas is the most effectual in destroying the infective activity of sputum from phthisical patients. Our first experiments with it failed because we exposed the sputum too short a time and used too weak chlorine-water. We found, however, that if the material were thoroughly exposed to chlorine gas (mixed with it), or thoroughly shaken or mixed with strong, fresh chlorine-water, it soon became innocuous, and animals inoculated with it would not become tuberculous.

In October, at a meeting of the Detroit Medical and Library Association, we showed a healthy guinea-pig which had been inoculated, on February 6, 1889, with chlorinated sputum, while a monkey and another guinea-pig, inoculated at the same time with sputum from the same case, but unmedicated, died in the ordinary way. The fact, however, of chlorine gas being so irrespirable and harmful even when diluted with a large amount of air, rendered its use for inhalation quite out of the question for a time. We have found, however, that when diffused in an atmosphere previously laden with spray of chloride of sodium solution, that patients could inhale large quantities of it without bad effects. Of the many substances used by hypodermic injections, we have found that iodine and iodide of potassium in solution with glycerin and distilled water (all chemically pure) are well borne by the tissues, and exert a marked effect on the course of some forms of phthisis pulmonalis. Our experiments with this combination of substances in 1889, produced terrible abscesses, which we discovered were due to impurity of the drugs, and using too much at first (there should be no residue when the crystals are submitted to sublimation).

Guinea-pigs or monkeys thus well iodinized will not take tuberculosis from inoculation! We have a monkey and several guinea-pigs that were iodinized before inoculation, still living—the control-animals being long since dead. This is also true of the use of the gold and sodium salt. Next to iodine for general use, and superior for some cases, is chloride of gold and sodium, which should be also chemically pure. The injection of this solution causes but little pain. It is most efficient when used alternately with iodine, or mixed with it in the proportion of one-twelfth of a grain of iodine and one-fiftieth to one-twentieth of a grain of gold and sodium. The best place to introduce the hypodermic needle is in the buttocks. The injection in this situation causes less pain, and there is less liability of the formation of abscess.

The injection of iodine causes a little more pain than the solution of gold and sodium. The mixture of the two solutions should be made slowly and carefully; too much of the iodine should not be

added, or the insoluble iodide of gold will be formed, which will cause abscesses. We have treated a large number of animals during the past year with very good results so far. We have thoroughly treated since the early part of September of this year up to December, about 25 cases of phthisis pulmonalis in the human being of different types, and 2 cases of general tuberculosis. The latter were advanced cases, and died—although in one there was decided mitigation in the course of the disease. Of the cases of phthisis pulmonalis, 4 were far advanced and died—one being a case of laryngeal phthisis. Four cases (of the subacute variety) not far advanced but showing caseation, etc., have been so positively benefited as to be called "cured." They have remained quite well and resumed their respective avocations. The remaining cases are still under treatment; two of them, however (one laryngeal phthisis and the other subacute pulmonary phthisis, sometimes called pneumonic phthisis), are so much improved that they will leave Harper Hospital in about a week. Of the remaining cases two were well advanced before entering the hospital, but are decidedly better. We have now 21 cases under these plans of treatment exclusively, about one-half of which have been under treatment but a few weeks, and most of them are doing well. We have treated quite a number of cases for only a week or two and then lost track of them; from some we have since heard that they were better. Necessarily many months must elapse and many more cases must be subjected to these plans of treatment before a conclusive clinical test can be attained. We have not as yet had experience enough to formulate any positive rules for the selection of one over another of these agents in the treatment of the different classes of cases. But we submit the following observations for guidance, which up to this time seem appropriate.

In all cases it is better to use the solution of iodine once daily, beginning with $\frac{1}{12}$ grain, and gradually increasing to $\frac{1}{6}$ or $\frac{1}{3}$ grain for about a week, unless symptoms of iodism, or a too rapid diminishing of urine, or expectoration supervene, in which event the gold and sodium should be used instead, beginning with one injection daily of $\frac{1}{50}$ grain, gradually increasing to $\frac{1}{15}$ grain. Cases which have a great deal of cough and little expectoration should be treated *chiefly* with the gold and sodium solution, if not *exclusively*. After a few days' treatment with iodine, cases showing active caseation (gurgling râles, large mucous râles, etc.) with great expectoration should have the chlorine inhalation as well. It may be administered every three or four hours from a face-shield inhaler, or, what is better, the patient should be kept in a room in which there is constantly diffused more or less chlorine with a spray of chloride of sodium. Then, after a week or so of iodine, such cases should receive injections every day, or on alternate days, of the two solutions mixed.

After the third week the injections may be diminished to every second or every third day. Patients with laryngeal phthisis should receive inhalations of chlorine from an inhaler, three times a day, until they complain of a general rawness of the throat, when it should be stopped for some days and inhalations of petrolina or olive oil given instead. Phthisical patients with pulmonary cavities, etc., should receive the inhalation of chlorine, if possible, directly after expectoration so that the gas may reach the diseased surface. The temperature usually keeps elevated for the first two weeks—indeed may go higher than with other plans of treatment. When persistently high it is better to substitute the gold and sodium solution for the iodine for a few days, when both may be used together. With sensitive patients it may be necessary, at first, to precede the hypodermic injection with one of morphine or cocaine. They must not, however, be added to either of these mixtures as a precipitate would follow. We give little or no medicine by the mouth; sometimes some calisaya mixture or compound tincture of cinchona to improve the appetite. Considerable perspiration is a pretty constant attendant on this treatment. The nourishment, it is unnecessary to say, must be looked after carefully.

A CASE OF LEPRA MACULOSA ET TUBEROSA.

By LOUIS A. DUHRING, M.D.,
PROFESSOR OF SKIN DISEASES IN THE UNIVERSITY OF PENNSYLVANIA.

Recently a case of leprosy, illustrating the macular variety, came to my notice in this city. The man presented himself for treatment, and at the time was entirely unaware of the nature of the disease. He had been under the care of a number of physicians, and had been treated for supposed syphilis and other affections, but no one had even intimated to him that the disease was or might prove to be leprosy. When told of the disease from which he was suffering he expressed great surprise, and even doubt as to the correctness of the diagnosis, for the reason that he had not for many years been in a leprosy country or district, and even then only as a traveller; and, moreover, because none of the other physicians who had treated him from time to time had so regarded the disease.

The notes of the case are briefly as follows:

J. A., aged forty-one years, and born in Sweden. There is no family history of interest. He was in Peru and Chili in 1868, and was in the merchant-marine service as a sailor from 1871 to 1888. In 1878, he was in Calcutta and Bom-

bay for a period of three or four months. He frequently went ashore while at Calcutta, but only once while at Bombay. He has never visited other leprosy countries, and during the past eighteen months has lived in a city near Philadelphia, working in shipyards and printworks. He has no idea concerning the origin of the disease, which made its appearance, he states, two and a half years ago, upon the left brow and on the posterior surface of the right thigh, in the same form as it now exists. At first the spots were so faintly discolored and thickened as to be barely noticeable, and they have gradually become more and more pronounced, and have greatly multiplied. At present the disease involves the entire face, the trunk, and extremities, and exists in the form of numerous rounded and ovoidal, coin-sized, dull-yellowish, and dusky-orange, smoky, coppery, and brownish-yellow macules, and tuberose and flat patches of infiltration. The latter are flat or elevated, and in some places even lumpy or nodular, as on the face. The disease is most marked on the face and back. (See cuts.) The face shows the peculiar heavy-looking, severe, leonine expression so characteristic of this disease, due to the tuberose infiltration and swelling of the cutaneous tissues, and the consequent sinking-in of the normal lines and creases of the skin. The eyelids are much thickened, and droop, as shown in Fig. 1.

There are no circumscribed tubercles present, either on the face or on other regions, the infiltrations, as stated, being in the form of diffuse or spread-out tuberose or flat lesions, such as occur in late syphilitic infiltrations and gummata. The macules and patches are distinctly anæsthetic—some more so, some less—the sticking of a needle into the skin causing no pain. The disease gives rise to no subjective symptoms, nor inconvenience beyond its presence and the consequent disfigurement, and his general health and strength remain good.

The disease portrays mainly the macular manifestation in an advanced stage. The lesions are numerous and extensive, and the entire force of the infective process seems to have expended itself on the skin. Some of the lesions on the trunk well illustrate the so-called morphœa of leprosy, as described by Erasmus Wilson and others of the older authors, and the resemblance to the ordinary morphœa simplex is so marked as to suggest that both diseases have a common starting-point in nerve complication, although, of course, of an entirely different nature. This I feel convinced of, and I have long held this view. Both kinds of cutaneous lesions are due to impaired or altered nerve supply, the one—lepra—to a known and definite cause, the other—morphœa simplex—to obscure and non-specific causes. Both are neuritic.

FIG. 1.

FIG. 2.

A piece of infiltrated skin was excised and prepared for the microscope. The examination was made by Dr. M. B. Hartzell, to whom I am indebted, with the following results: The lesion from which sections were made for microscopical examination was situated upon the posterior surface of the upper part of the

right thigh, and was one of the earliest signs noticed by the patient, and was therefore one of the oldest. No pathological changes of any kind were found in the epidermis. In the corium an abundant diffuse infiltration of small round cells existed, with here and there slender tracts of unaltered connective tissue. This cellular infiltration was seen to be uniformly distributed throughout all parts of the corium, except that immediately beneath the papillary portion, where it was completely absent. In this part of the corium, beyond a few dilated lymph spaces, no change was noticed. No so-called lepra cells were anywhere found. Numerous sections, stained according to the methods of Weigert and Ziehl, were carefully examined for bacilli, but none were seen.

The man was seen only once, having subsequently failed to return for advice and suggestions as to treatment. The case is interesting from several points of view. First, as to the date and origin of the disease, and as to the mode of infection, upon which questions nothing positive can be stated. The natural supposition would be that the disease was contracted in India, and the only point which renders this doubtful is the long period—ten years—between the time of exposure and the first manifestations. But, it is entirely possible, and even probable, that the disease manifested itself insidiously, perhaps for several years before the attention of the patient was called to it. I think this highly probable, more especially as the man is by no means intelligent or observing. There is no history of contact with other lepers. The patient was amazed when informed of the true nature of the disease, which he had never suspected, and appeared to be anxious to place himself under treatment.

The second point of interest relates to the diagnosis. As stated, he had been seen by many physicians, none of whom informed him as to the nature of the disease, nor instituted or suggested any systematic course of treatment. The disease is undoubtedly lepra, but could be, I can well see, confounded with several affections, notably with granuloma fungoides (mycosis fungoides) in its early stage, to which it bears resemblance, also the infiltrated form of tubercular syphilis; but the wide distribution and the numerous areas of disease, and the bronzed tint of the skin, ought to be sufficient to exclude the latter disease. On the other hand, the dusky-yellowish color is not unlike that seen in granuloma fungoides; but the variegated colors as well as the inflammatory symptoms common to that disease are wanting.

Surgical Dressing for Soldiers.—The *Medical Press and Circular* states that in India the government has authorized a packet of first field-dressing in lieu of a bandage, to be given to soldiers whenever the army is ordered out for active service. Officers also receive the dressings.

REPORT OF A CASE OF GUNSHOT WOUND OF THE ABDOMEN, WITH THREE MESENTERIC AND SIXTEEN INTESTINAL WOUNDS; ABDOMINAL SECTION; RECOVERY.[1]

By A. B. MILES, M.D.,
SURGEON TO THE CHARITY HOSPITAL, NEW ORLEANS, LA.

On the morning of September 11, 1890, F. H., while carelessly handling a thirty-two calibre pistol, shot himself in the abdomen, the missile entering in the median line at a point midway between the umbilicus and the pubes. An ambulance was at once summoned, and within half an hour the patient was placed in the operating-room of the Charity Hospital.

His physical condition was, in every respect, excellent. He was a young white man, aged twenty-four years, of slender frame, but strong, and weighed about one hundred and thirty pounds. Fortunately, he had eaten sparingly for several days, owing to some slight indisposition. There were evidences of shock, but not in a marked degree. His pulse was 108. He complained of abdominal pain only.

Having determined that the ball had entered the abdominal cavity, and being convinced that the missile delivered at such a short and direct range, had inevitably injured the viscera or vessels, we at once decided upon active surgical treatment.

The operation was performed in the presence of our resident medical staff, and with the aid of Dr. J. D. Bloom, the assistant house-surgeon, who also with the assistance of Mr. E. D. Martin, conducted most of the after-treatment during my absence from New Orleans.

Median abdominal section was performed, the incision being four or five inches long. There was considerable blood in the peritoneal cavity, and the perforations were soon revealed in the protruding intestines. We at once instituted a systematic search for the bowel wounds, passing the small intestine in review from the beginning of the jejunum to the end of the ileum. The bullet, after entering the cavity, ranged a little to the left, wounded the mesentery in three places, perforated the small intestine sixteen times, and lodged somewhere in the deep muscles of the back. The man having eaten but little for several days, the intestines were practically empty, and this fact alone explains the number of intestinal wounds. A bullet, passing in any direction, could scarcely inflict so many wounds in a bowel even moderately distended. The condition which explains the large number of mesenteric and intestinal perforations also contributed very materially to the successful termination of the case, for aside from a small amount of mucus and blood, nothing escaped from the bowel wounds, and all operators know that in such cases no accident more seriously complicates an operation than fæcal extravasation.

The operation was necessarily very tedious, lasting a little more than two hours. The mesenteric vessels were bleeding and their ligation consumed

[1] Read, by title, before the Southern Surgical and Gynecological Association, November 12, 1890.

a considerable part of the time. The intestinal wounds were closed with Lembert sutures of fine silk passed in the direction of the bowel. This plan seems least calculated to contract the calibre of the gut. Hæmorrhage having been arrested and the visceral wounds closed, the peritoneal cavity was douched with sterilized hot water, the abdominal incision sutured with silk and the usual antiseptic dressings of the hospital were applied.

The dressing was removed on the eighth day and the deep abdominal sutures taken out; the superficial sutures were removed on the twelfth day.

On the evening of September 11th, the day of the operation, the temperature registered 94⅘° F., and the pulse was 115. A hypodermic injection of sulphate of morphine ¼ grain and sulphate of atropine $\frac{1}{150}$ grain was administered.

On the evening of the following day the temperature rose to 102° F.; the pulse to 150 per minute. These changes were attributable to our generosity in feeding. The above temperature, representing the highest points of the record, was promptly reduced by 10 grains of antipyrine administered hypodermically. On several subsequent occasions the temperature exceeded 101° F., but during confinement in bed it was usually about 99° F. The pulse was usually in accord with the temperature. After the first week, however, the pulse often beat about 60 and occasionally less (54) per minute.

From the second until the seventh day after the operation the patient was nourished exclusively by rectal alimentation. Only water, in quantities of half an ounce at a time, was given by the mouth. Food by the mouth was allowed on the seventh day, but was given very sparingly—teaspoonful potions of chicken tea, boiled milk, or Dacrois's elixir. The quantity of nutriment by the mouth was gradually increased until the thirteenth day, when the patient was given a breakfast of a soft-boiled egg, crackers, and a cup of coffee. In the meantime the little food given in the natural way was supplemented by rectal feeding.

On September 30th, dietary restrictions as to quality were removed, and the patient was only guarded against an excessive quantity.

On the fifth day after the operation the intestinal gases escaped naturally, and on the twentieth day there was a voluntary fæcal evacuation.

The patient remained in the hospital until October 18th, and from that date until the present writing, November 10th, has remained perfectly well. He affirms that his alimentary functions are in every respect perfectly normal.

This report is intended simply to add one more case to the growing list of successful enterorrhaphies for gunshot wounds, the only remarkable feature in the case being the unusual number of peritoneal and intestinal perforations—nineteen in all.

As we go to press, we learn that the President has appointed Dr. Charles Sutherland Surgeon-General of the United States Army.

LOCALIZED CENTRES IN THE OPTIC THALAMI.

BY HUGO ENGEL, A.M., M.D.,
CONSULTANT ON NERVOUS DISEASES AT ST. JOSEPH'S HOSPITAL, OF PHILADELPHIA.

J. L., aged forty-three years, came to my clinic at St. Joseph's Hospital, May 5, 1890. Family history showed no hereditary taint. Patient had passed through the diseases incident to childhood without any lasting injury, and remained in good health until twenty-three years of age, when he had typhoid fever. The attack was severe and left him in a weakened condition for a year. Some paretic symptoms, the exact character of which could not be gleaned from the description, affected his lower extremities for several months during the earlier part of convalescence. At last, however, the patient completely recovered and remained well until his thirty-seventh year, when he contracted a primary, single, and indurated venereal sore. This was some months in healing, and was early accompanied by swelling of one of the left inguinal glands. The bubo proved stubborn and, notwithstanding various irritating injections into the enlarged gland, suppuration did not ensue. Within six months after the healing of the initial sore febrile symptoms ushered in an exanthem of roseola syphilitica, and, two weeks later, psoriasis palmaris, mucous patches over the tongue and the lining membranes of the cheeks and lips and angina luëtica formed the phenomena of a typical attack of secondary infection. Whether in consequence of a want of proper specific treatment in the hands of an irregular practitioner, or whether due to the virulent character of the poison, could not be determined, but the constitutional symptoms continued unabated for nearly a year. By the end of that period the eruptions upon the skin and mucous membranes had disappeared under the treatment of a physician in New York, but the throat affection did not heal until deep ulceration had destroyed parts of the palate, leaving an ugly scar.

The therapeutic measures directed by the physician in New York for the cure of the systemic infection evidently were very successful, as the patient remained free from all manifestations of the specific virus for about four years, gained decidedly in weight, and enjoyed the best of health. But he then began to suffer from headache, which always made its appearance about five o'clock in the afternoon, and gradually increased in severity as night approached. During the next few months the headaches came on progressively earlier in the afternoon, still becoming more intense toward evening, and becoming so severe at bedtime that it prevented him from falling asleep until between one and two o'clock in the morning, when the pain ceased, enabling him to obtain about five hours' rest. He never had the headaches in the morning.

He underwent treatment for supposed malaria, then for neuralgia, and finally for chronic meningitis, but without securing the least relief. After he had had the headaches for about three months he experienced a peculiar nervousness, accompanied by such a feeling of lassitude as completely to incapaci-

tate him him for work (that of a foreman in a large machine-shop). The nervousness seized him every afternoon very soon after the beginning of the headache, but these phenomena, as well as some giddiness, which frequently made its appearance about the same time, were ascribed by him and his physicians to the deleterious influence of the torturing headache and the loss of sleep entailed thereby.

The new symptoms also gradually became more intense, until, drifting from one doctor to another in his endeavors to rid himself of his complaint, he finally landed in my clinic. The group of symptoms enumerated had then been present for nearly a year. Judging from the suffering which the man had undergone, one would have expected to find the consequences of it stamped upon his face, and that his whole system would show the inroad of the disease, but the contrary was noted. When I first saw him he weighed one hundred and seventy pounds, his height being five feet nine inches, and his florid complexion and well-nourished physique gave no evidence of a serious malady. But the skin over the lower part of the forehead between the brows and that over the temples, had that peculiar dirty hue—a yellowish-brown tint in his case, but in other cases varying with the complexion of the individual—which experience has taught me is almost pathognomonic of the luëtic virus when this attacks the nerve-centres, though it is probably met with in most instances of systemic infection by the syphilitic poison.

As I could discover no organic lesion aside from the luëtic affection of the brain which did not appear to me so urgent as to make the postponement of the specific treatment for a few days a weighty matter, and as his digestion was somewhat faulty, and as he did not lead the most regular life, I concluded to place him first under the most favorable hygienic conditions, and to regulate his diet and improve his digestion. It is here that I made a mistake by not recognizing the great danger that he was in.

I asked the patient to return in three days, but I did not see him again until a fortnight later, when his wife called on me and begged me to visit him. Fearfully had the picture of the disease changed within that short period of time! When he came to the clinic there was nothing in his features to denote illness, while two weeks later death had stamped its ineffaceable mark upon the countenance of the man. After a long and patient inquiry I elicited the following:

Three days after he had left the clinic, on awakening in the morning, he felt confused and noticed, on rising, that he staggered, which he ascribed to the fact that he had no feeling whatever in the sole of his right foot. He then also observed the absence of feeling in his right arm, and a further investigation proved to him the total disappearance of all tactile sense on the entire right side of his body. While eating his breakfast he made the discovery that the senses of smell and taste on the right side had suddenly left him. He was sure that these symptoms were not present when he cleaned his teeth before eating and when he washed and dressed himself. He always had been in the habit of using a mouth-wash flavored with teaberry, and he was certain that he would have noticed the absence of taste and smell, and that he would then have examined further, as he did later to see whether hearing and sight were affected, for he was by nature a close observer. Ignorantly ascribing the symptoms to some transient effect of the medicine which I had given him, and even feeling encouraged, as his headache and giddiness, as well as a great deal of the nervousness and lassitude, remained away for the first time in a year, he failed to send for me.

This state of affairs lasted for eight days. On the afternoon of the ninth day, within fifteen minutes, he lost feeling, smell, and taste on the left side also, and very soon after became deaf in both ears. His wife now went to the hospital for me, but was informed—it being Tuesday—that the clinic for nervous diseases would not open again till Friday, though I might be seen at my house. Upon reaching home again she was persuaded by him to wait until Friday, he remarking that he felt generally so well that he did not care to trouble me. But Thursday evening the most alarming phenomenon occurred: he suddenly became blind in both eyes. It was then that they hastened to call me.

There is no doubt in my mind that the symptoms occurred exactly as named. The man first had a primary sore, then a bubo, and within half a year secondary luës, ushered in, as probably all the more virulent cases are, by roseola, preceded by fever. For a year these secondary manifestations did not yield to treatment, but the patient after that enjoyed good health and freedom from symptoms of syphilis for four years. Then headache set in with nocturnal exacerbations, giddiness, nervousness, and general lassitude, the forerunners of nearly all varieties of cerebral luës. When these symptoms had existed for about a year the tactile sense suddenly became extinguished on the right side, followed within an hour by loss of smell and taste on the same side. The senses of touch, smell, and taste, within a few days, were also lost on the other side, and deafness developed in both ears, followed in a few days by complete blindness of both eyes. The headache, vertigo, and nervousness had almost totally disappeared when the special senses became affected.

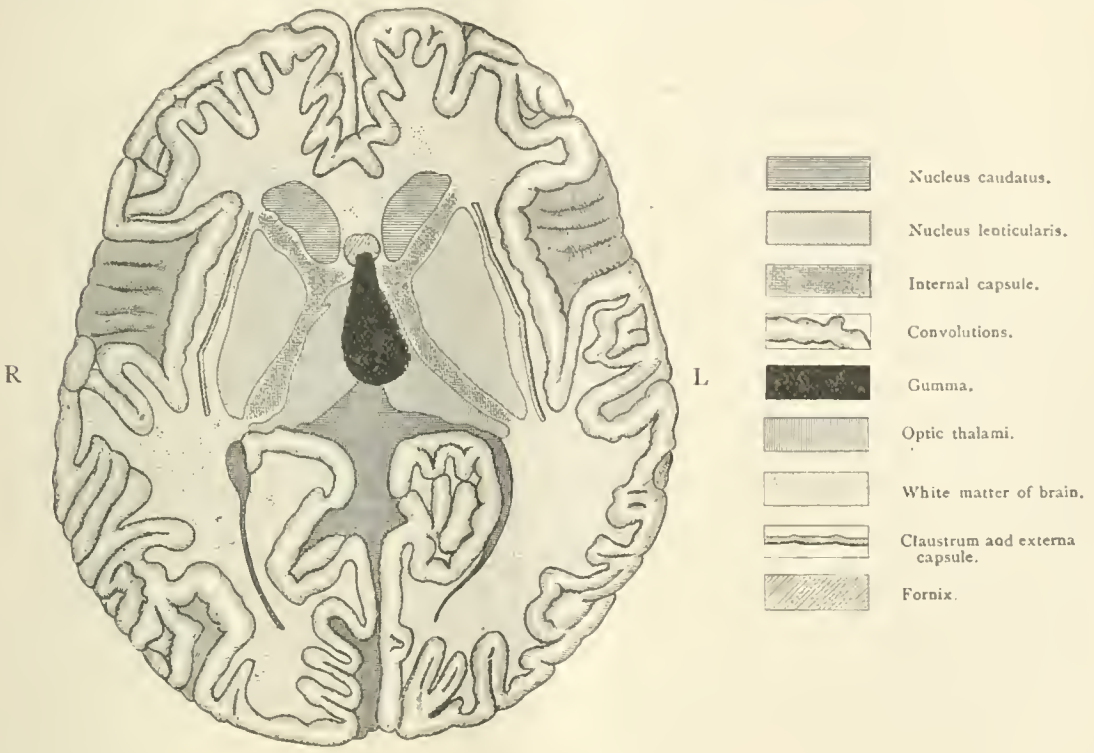
During Thursday night the patient was taken with convulsions, or, rather, he fell into *l'état de mal*, during which he died. Immediately preceding the fatal issue he gained consciousness and said, "What has been the m——?" probably intending to continue, "matter with me?"

At that moment the right pupil became widely dilated, the upper lid of the same eye dropped and remained in the state of ptosis, and finally a few lightning-like twitches of the facial muscles announced another convulsion, during which death occurred. The convulsions themselves were absolutely bilateral, and if they presented any especially characteristic point, it was the short duration of the tonic rigidity.

The patient's family assented to an autopsy after a great deal of persuasion, and with the proviso that under no circumstances was I to remove or permit

to be taken away any part of the body. Various motives, which it would be out of place to discuss, but which were more or less rooted in superstition, determined the wife to insist upon that condition. Besides two brothers of the deceased, a priest carefully watched Dr. Louis Gruel, the chief of my clinic, and myself, thus making it impossible for us to remove clandestinely any tissue, even had we been so inclined.

Autopsy.—Only the head was opened. The blood-vessels were rigid and in the state first described by Heubner, of arterio-sclerosis syphilitica. Characteristic newgrowths had commenced to form within the lumen of the basilar, middle meningeal, and other large arteries at the base of the skull. At the points where the neoplasms were located the vessels were greatly narrowed—the opposite of what occurs in senile sclerosis, in which the stiff walls prevent the vessels from collapsing and the lumen is widened. Although every part of the encephalon was carefully examined microscopically, nothing else abnormal was found until the lateral ventricles were opened. Here was a neoplasm which had formed in the fornix and from thence spread over the optic thalami; the growth being older and more advanced on the left than on the right side. (See cut.) It had the usual characteristics of gummata. As I am not an experienced draughtsman I have taken the normal parts of the drawing from Ranney's and Erb's illustrations. The cut explains itself and clearly shows the extent of the gumma.



REMARKS.—Observers agree that the pillars of the fornix unite the thalami with the cortical centres of smell and taste, and the course of the fibres and their evident prolongation into the respective temporo-sphenoidal convolutions seem to demonstrate the correctness of this view. Fournier has shown that the fornix also connects the thalami with the cortical centres of tactile sensibility. Motor symptoms are always absent when the thalami alone are involved, and in the cases reported as an evidence of motor disturbance, due to disease of a thalamus, the lesions were so near the internal capsule (Ranney)—*i. e.*, its thalamo-lenticular portion (Spitzka)—that the cause of the motor phenomena in these instances is easily explained.

The newgrowth in the case reported here evidently began in the portion of the fornix where, at the posterior end of and between the two caudate nuclei of the corpora striata, it is connected with the most anterior part of the optic thalami. The patient's first symptom was loss of tactile sense, followed by loss of smell and taste on the right side. These symptoms agree with the result of the autopsy, which showed that the disease was more extended and evidently older on the left side of the fornix and in the left thalamus.

Luys has made the most thorough investigation of the functions of the thalami. He discovered in them four isolated ganglia, and Arnold, who at first affirmed the existence of only three, has since been convinced of the presence of a fourth ganglion. These ganglia are arranged in an antero-posterior plane and form successive tuberosities upon the

thalamus, giving that body the appearance of a conglomerate gland (Ranney).

Proceeding from before backward these ganglia are:

1. Corpus album subrotundum. This is the most prominent of all and is especially developed in dogs, in which the sense of smell is very acute. By means of the tænia semicircularis it is also connected with the roots of the olfactory nerve. All peripheral olfactory impressions are first condensed in this ganglion, before they radiate toward the cortex.

2. The second centre is said by Luys to be connected with the organs of vision. But the majority of observers now agree, that the posterior part, the pulvinar, together with the external geniculate bodies, is related to the visual tracts, which pass on to the cortical centres of vision in the occipital lobe (cuneus, etc.), while the second ganglion, the fibres of which connect with the side of the internal geniculate body, is brought in direct communication with those temporo sphenoidal gyri which form the cortical centre of hearing.

Unless a microscopical examination should have shown pressure on other parts or a gradually-extending degeneration of fibres composing portions of the internal capsule, or unless capillaries situated in other regions were the seat of the endo-arteritis first observed by Finger—assumptions which would not agree with the group of symptoms presented *intra-vitam*—the case reported would prove the general correctness of Luys's views, excepting as far as they relate to the second ganglion; concerning the latter the case would confirm the statements of the later authors (Serres, Fleichsig, Wernicke, Monakow, etc.) referring to the pulvinar.

After abolition of the tactile sense and that of smell and of taste, hearing was lost, and later the power of vision; the gumma evidently grew with astonishing rapidity in an antero-posterior direction. If the second ganglion of Luys were connected with the visual apparatus, blindness should have preceded the deafness.

3. The third ganglion, exactly situated in the mathematical centre of the thalamus (Ranney) governs in some way general sensation. It probably is the automatic centre for general sensation or for some special part of sensation, such as touch, so that some impressions belonging to the category of general sensation under certain conditions do not reach the cortex, but are interpreted here, and such impressions proceed further only if the cortical centres (in the parietal convolutions) either exert an inhibiting influence on those situated lower down, or so stimulate them as to cause a further transmission of the sensory impressions.

The lower gray masses seem to have the same relation to the various afferent and efferent tracts that the strengthening batteries possess to a long telegraphic relay consisting of a number of stations. The current from the cells at the first station is strong enough to carry the current to the next; if the current shall proceed further, it must first pass through wires which bring to it increased electromotive force obtained from another battery, thus enabling the impulse to go on its way undiminished in power. The cells in the cortex must influence in some such way all the various cells situated in the same tract but beneath the cortex. It is then by inhibition or stimulation that an impression is either stopped at some point where the local function of the cells transform the impression into motor acts, or it proceeds to the end and becomes a conscious impression, to be registered in a cortical cell, associated with others and simply recorded as memory—as the wax cylinder of the phonograph retains the indentations made upon it by the recording needle of the diaphragm, which in its turn is set in motion by the waves of sound—or is transformed and interpreted as conscious volition with its efferent result: a motor impulse.

Thus, in an English setter dog, when arriving on the field where partridges are concealed, the cortical centre in the temporo-sphenoidal gyri—probably the most anterior portion of the middle temporal convolution and perhaps the same part of the inferior—sends an impulse to the ganglion of smell in the thalamus and this sets in motion the complicated apparatus which enables the dog to discover the hidden birds, and he then automatically performs his duties.

I omitted in the case of J. L. to examine especially into all the various disturbances of general sensation that may have existed, but he was not conscious long enough to allow me to make such an examination successfully. If the middle ganglion is related to general sensibility, almost all sensation should have been destroyed, unless such afferent impressions pass along a tract which, forming a part of the internal capsule—the third bundle antero-posteriorly from the knee in the thalamo-lenticular portion, between, therefore, the pyramidal and the speech tracts (Wernicke)—proceeds cephalad without connecting with the thalami, ending in the parietal convolutions.

If specific treatment energetically and systematically carried on, had been commenced at once, when J. L. first came to my clinic, the growth of the neoplasm might have been prevented or brought to a standstill—in the latter case absorption would probably have ultimately occurred. His failure to return in three days made the employment of antiluëtic treatment impossible, and thus may be said to have been directly responsible for the sudden fatal issue.

507 Franklin Street.

ON SOME RELATIONS BETWEEN THE HEART-BEAT AND THE VISCERAL CIRCULATION.

By HENRY SEWALL, M.D., Ph.D.,
of Denver, Colorado.

To the popular mind the heart is, *par excellence*, the central organ of animal life, the engine which keeps the vital forces in continuous play, and the sensitive mechanism of which is readily thrown out of gear. Exact physiological study has in no way diminished the importance in the economy of the cardiac motor, but it has developed the fact that nearly every "functional" disturbance or physiological modification in the activity of the heart is brought about by causes operating not directly on the heart-tissue, but in an indirect way through the nervous system, and especially the vasomotor mechanism.

Every working physiologist has at times been astonished at what may be called the "toughness" of the heart, its tolerance of injury when considered apart from the rest of the body. Among a class of students, wonder is always excited by the spectacle of a living frog's heart isolated from the body, and supplied with a nutrient current of defibrinated blood or diluted blood-serum, beating regularly for hours, and performing an amount of work which would give it a high grade of efficiency among artificial machines.

It is not the design of this paper to enter into a full discussion of the physiological mechanism of the heart, but there are certain general facts concerning it, whether old or new, which have been only imperfectly transmitted from the laboratory to the clinic, and which must be considered if the interdependence of the cardiac and other physiological functions is to be regarded. It may, therefore, not be thought out of place to sum up once more some of the well-known facts of cardiac physiology as a basis for the hypothesis which it is the object of this article to develop.

One of the most surprising facts connected with the study of the heart is the small amount of nutriment on which the organ will continue to perform its work. If a frog's heart be removed from the body, and allowed to remain empty, it will usually cease beating within half an hour; but if a very weak solution of mineral salts, having the qualitative and quantitative relations of the salts in the normal blood plasma, be passed through the heart cavities, strong pulsation may be kept up for five or six hours. If to the salt solution there be added an exceedingly small proportion of appropriate albuminous matter, the heart may continue to beat for a day or two. On one occasion I observed a frog's heart, suspended in a Roy-Gaskell tonometer and supplied by a current of diluted defibrinated blood, keep up its pulsation for more than three days.

It has been found that the addition of drugs, such as acids or alkalies, even in so small a proportion as 1 part to 20,000 parts of the fluid circulating through the isolated heart, profoundly modifies its pulsation, and we should, *à fortiori*, expect that deleterious substances, though present in the normal blood in inappreciable quantities, would have a distinct effect on the action of the heart.

What particularly concerns us here, however, in relation to the direct action of the blood on the heart, is not so much the nutritive value of the fluid as its influence in mechanically distending the cardiac walls; or, in other words, in determining intra-cardiac blood-pressure.

About twelve years ago it was announced by H. P. Bowditch, that if the ventricle of a frog's heart be crushed in a line across the middle, by a pair of small-bladed forceps, the apex of the organ, being thus removed from its physiological connection with the rest of the heart, will remain empty and quiescent, the basal portion alone carrying on the work of circulation. But Foster, in repeating this experiment, found that if the intra-cardiac pressure were raised by clamping the aorta, the previously empty apex would fill with blood and commence rhythmical pulsations.

Many other facts discovered in the laboratory testify in favor of the proposition that increase of intra-cardiac pressure, within limits, acts as a stimulus to the motor mechanism of the heart.

Not only does the intra-cardiac blood-pressure, which is determined, other things being equal, by the ratio of the inflow to the outflow of blood through the heart, have a most important influence on the energy developed by the active isolated organ, but it profoundly modifies the susceptibility of the heart to the reflex impressions which are probably continually pouring into it along the extra-cardiac nerves.

Nearly ten years ago, in association with F. Donaldson, Jr., of Baltimore, the writer published,[1] from the laboratory of the Johns Hopkins University, an account of some experiments undertaken with a view to ascertain the exact relations between the variation of intra-cardiac blood-pressure and the intensity of inhibitory action which the cardiac branches of the pneumogastric nerves exercise over the heart-beat.

Most of our experiments were performed on the "slider" terrapin, the heart of which consists of four chambers, namely: a venous sinus, which collects the blood from the tissues and conducts it into one of the two auricles; a second auricle, which receives the aërated blood from the lungs; and a single ventricle, which receives the blood from both auricles. In our experiments the heart was supplied

[1] Journal of Physiology, vol. iii., Nos. 5 and 6.

through either auricle by a current of artificial diluted, defibrinated blood, the pressure of which in the heart could be maintained at any desired degree by changing the level of the Mariotte's flask which served as a reservoir for the blood. The vagi nerves being isolated and placed on the electrodes of an induction apparatus, it was ascertained what strength of current was able just to produce an inhibitory slowing of the heart-beat. The intra-cardiac pressure was then changed, and the effect of stimulation was again tried. The invariable results may be stated thus: With increase of intra-cardiac pressure there is a diminution of the inhibitory action of the vagus nerve on the heart-beat; if the intra-cardiac pressure be sufficiently increased, the inhibitory power of the vagus is, for a time, wholly lost. On the other hand, the vagus inhibitory action is intensified by lowering the intra-cardiac blood-pressure. We found this reaction to be extremely delicate, for the susceptibility of the heart toward inhibitory impulses travelling along the vagus was altered by very slight variations in intra-cardiac pressure, as well represented in a column of blood one centimetre or less in height. We endeavored to carry out similar experiments on the dog's heart, isolated according to the "Baltimore method," and though, owing to the vastly increased complexity of the physiological conditions, the results were unsatisfactory, they plainly pointed to conclusions similar to those arrived at in the case of the terrapin.

Subsequently the writer accidentally obtained an interesting confirmation of the foregoing views of the pressure-inhibitory relations in the mammalian heart. A calf was on the operating-table of the laboratory; the excitement of the animal could not be controlled by any reasonable amount of anæsthetic; its circulation was abnormally active and blood-pressure high. It was found that the vagi, stimulated either singly or together by powerful induction currents, were absolutely without control over the rate of the heart-beat. When, however, the blood-pressure was lowered by moderate bleeding, the inhibitory influence of the stimulated vagus was readily manifested.

It is well known among physiologists that it is impossible to produce fatal syncope in animals by artificial stimulation of the peripheral ends of the cut vagi; yet cases are not wanting which indicate that the "shock" which causes death in many casualties is but the expression of powerful reflex inhibition of the heart-beat through the pneumogastric nerves. Thus, Goltz cites the case of a workman who, while asleep after his dinner, was struck on the abdomen by a board in the hands of a playful comrade. The sleeper died instantly, but post-mortem examination failed to show any anatomical lesion. Goltz uses this case as an illustration in the human animal of the *klopfversuch*—*i. e.*, reflex inhibition of the heart-beat by sharply tapping the intestines—which he had, for the first time, just demonstrated on the frog. It seems exceedingly probable that the reason direct stimulation of the vagi in an animal on the operating-table does not cause death, while reflex inhibition through irritation of the sympathetic system under physiological conditions may do so, lies in the fact that in the former case the cardiac motor system alone is directly affected, the respiratory and vasomotor mechanisms still keeping up their work with even exaggerated activity, so that the heart soon becomes loaded with blood which is squeezed out of the systemic vessels by the spasm of their muscular coats. Thus, in a short time the intra-cardiac tension is so elevated that the inhibitory impulses descending the vagi fall into a motor system so excited as to be insensitive to their influence.

On the other hand, in the case of reflex inhibition, the blow which momentarily stops the heart, at the same time paralyzes the vasomotor mechanism so that the blood collects and stagnates in the widely-dilated vessels of the abdomen; the under-filled heart then lacks the pressure-stimulus of inflowing blood, and, finally, the failure of nutriment in the vital centres is followed by a fatal decrease in their irritability.

Previously to the work referred to above, performed by Donaldson and myself, Ludwig and Luchsinger[1] had carried on somewhat similar experiments.

These authors made the interesting observation that when the temperature of the isolated frog's heart was artificially elevated the effect was to annul the inhibitory influence of the vagi. This suggests, of course, that in fevers the regulating influence of the vagi may be lost in a similar way.

As regards the stimulating effect of intra-cardiac blood-pressure, an interesting fact presented itself in the course of the experiments which have already been cited. The artificial supply of blood was led to the heart by a canula which was tied either in a pulmonary vein or in the sinus venosus, and thus only one auricle directly received the pressure of the inflowing blood, the other auricle being but imperfectly distended by leakage through the cardiac valves. A frequent, if not constant, result of this circumstance was a want of synchronism in the contraction of the two auricles; the systole of the more distended auricle perceptibly preceding that of the less distended auricle. That is to say, increase of the diastolic intra-cardiac blood-pressure in any chamber of the heart hastens the rhythm of pulsation in that part. Building on this fact, we can hardly doubt that in the complex relations under which the heart acts in the normal body, the

[1] Pflüger's Archiv, Bd. xxv.

balance of intra-cardiac diastolic blood-pressure in the two auricles is subject to frequent fluctuations, which must be attended by a more or less marked alteration of rhythm in the action of the various cardiac chambers. Such an event would offer an interesting explanation of the origin of those temporary heart-murmurs which auscultation one day reveals and the next finds wanting. Thus it is believed with reason that in the normal cardiac cycle, so soon as the ventricles have emptied themselves, and when the common diastole begins, the blood stored in the auricles immediately begins to flow onward with the effect of floating up the auriculo-ventricular valves until they nearly meet; then, at the end of the common diastole comes the short, sharp stroke of auricular contraction, which seems to shoot a current of blood down through the middle of each ventricle, which causes a reverse current to pass along the ventricular wall, lifts the valves and brings them into firm contact; at this instant the systole of the ventricle begins and regurgitation is prevented by the tightly-closed valves.

Suppose, however, that the rhythm of movement of the auricle and ventricle is altered by the fractional part of a second; in this case the auriculo-ventricular valves will have rebounded from their first closure when the ventricle begins to contract, and as a necessary result there will be a regurgitant current of blood and an audible murmur. Any sudden alteration in the volume of blood flowing through the lungs in the normal body would be followed by a corresponding change in the pressure within the left auricle, and give rise to the conditions sufficient to disturb the rhythm of movement in the different parts of the heart.

Such are some of the influences which may cause an alteration in the rhythm of the heart-beat by direct action on the organ. In addition, it may suffice to recall briefly the fact that the nerve-filaments which connect the heart with the central nervous system by way of the vagi and sympathetic nerves, contain physiological fibres of varied function, and which in the normal body are in nearly continual activity.

It has long been a familiar fact, and one already mentioned, that certain nerve-filaments arising in the roots of the spinal accessory, and proceeding to the heart by way of the pneumogastric trunks, carry impulses which exert a cardio-inhibitory influence; that is, stimulation of them causes a slowing of the heart's rhythm, or even a cessation of the beat. It is, perhaps, less generally known that fibres having an opposite or accelerator function, reach the heart by way of the sympathetic system. Excitation of these causes a quickening of the heart-beat.

In addition there has been established within the last few years the existence of two other sets of cardiac nerve-fibres; one of these, when excited, causes a progressive weakening or loss of power in the heart-beat, without alteration in the rhythm; while stimulation of the other set produces the converse effect, or augmentation in the energy of the heart's contraction. All these nerve-fibres belong to the efferent group of nerves; that is, they transmit impulses only from the central nerve-system to the heart.

Of afferent nerves, which carry impulses from the heart to the brain, we as yet know with certainty only one variety, the so-called *depressor* nerve, which, when the heart is over-distended with blood, causes a reflex enlargement of the splanchnic vascular area by inhibition of the vaso-constrictor nerve-centre, thus lowering the resistance against which the heart must empty itself.

But there is little doubt that there exists a full set of afferent fibres corresponding in function with the efferent nerves that have been mentioned.

Such is a brief *résumé* of some of the present certainties of cardiac physiology.

The therapeutics as well as the pathology of the circulation can have a sure foundation only in a physiological scheme which embraces every functional relation of organ to organ and cell to cell. It is this belief, at all events, which is offered as an excuse for the presentation of laboratory data as a basis for clinical inference.

In no organs of the body should we, *a priori*, expect to find more frequent causes of disturbance in the circulation than in the abdominal viscera. Into their vascular area might easily be drained all the blood in the body; their calls on the output of vital energy are often irregular and excessive; they are more or less continuously subjected to the influence of poisons physiological and non-physiological; the pressure of a loaded colon and rectum may at any time offer a serious obstacle to the normal current of blood.

The rate and completeness of the circulation, and consequently the character of the heart-beat, must obviously be influenced by each of these conditions; and it is not surprising that long ago there should have been recognized an intimate relation between the state of the bowels and certain symptoms derived chiefly from the circulation, such as vertigo, mental depression, disturbance of vision, flushings, palpitations, and coated tongue; a group of symptoms which presents itself so frequently as to lead the medical attendants of a certain dispensary to abbreviate the prescription indicated into

R.—Shotgun No. 2.

which being interpreted reads:

R.—Hydrag. chlor. mite . . . 5 grains.
S.—Take at bedtime.

and

R.—Magnes. sulph. . . . . ℥ss.
S.—Take in half a glassful of water before breakfast.

In other words, it has been found that simple unloading of the bowels, together with an "alterative" effect of the cathartic, suffices to restore the physiological tone.

It is, however, quite another group of symptoms, the consideration of which has given occasion for this paper. In this group the phenomenon of "heart failure" is most prominent, and I venture to believe the cause would by no means generally be ascribed to the state of the visceral circulation.

The symptoms referred to vary in intensity from a simple feeling of faintness or "goneness" with infrequent, weak, and perhaps irregular pulse, and rather labored, slow respiration, to an attack which in its appearance now resembles syncope, and again somewhat simulates coma.

These phenomena are not necessarily preceded by special symptoms nor by a state of unusual constipation. Patients so suffering have presented an account of more or less frequent recurrence of the attacks, with a history of some previous decided liver derangement, such as that associated with congestion or a malarial attack. Nearly all the cases which have been noted were those of patients in different stages of phthisis; this was, probably, in part due to the large proportion of phthisical patients in the neighborhood where these observations were chiefly made; in part, also, to the modified metabolism and circulatory resistance of the liver in this disease. In no case could any sign of heart lesion be discovered.

The attacks lasted, roughly speaking, from a few minutes to five or six hours, and then gradually subsided.

Unfortunately, in only one case did I witness the disturbance while at its height. In this instance the respiration was deep and labored, and only ten or twelve per minute; the eyes were fixed and staring; the face pale or ashy, and rather drawn and pinched; consciousness was incompletely preserved, and the pulse was weak and slightly rapid. In general, the pulse is characterized rather by weakness than infrequency, and the phenomena, as a whole, seem to indicate morbid feebleness in the circulation and deficient aëration of the blood. The exhibition of cardiac stimulants afforded rather incomplete and temporary relief, and after such treatment the attack might be repeated within a few hours or days; such has been the result even when digitalis was regularly taken in the interim.

On thinking over the clinical history presented by one of these cases, I remembered the picture offered by the dog's heart beating in the opened chest, and the powerless, flapping, spasmodic movement brought about in the organ when the blood-supply was diminished by clamping the venæ cavæ. Following out the analogy it seemed not improbable that the circulatory disturbance in the human subject was likewise the result of diminished blood-flow to the heart. Supposing this to be true, the suggestion was obvious that such a condition depended on a morbid state of the visceral circulation, and the line of treatment indicated was evidently to use the means at command to modify the blood-current through the abdominal organs.

Unloading the bowels by one means or another not only removes a possible mechanical hindrance to the circulation and empties the gland-ducts of their secretions, but the peristalsis excited is, undoubtedly, a most powerful motor factor in the passage of the blood through the portal system.

At all events, in each of the half-dozen cases of what, for want of a better name, I have thought best to call "functional heart-failure," it has been found that judicious catharsis, or rather laxative treatment, has succeeded in giving the surest and most nearly permanent relief from the appalling symptoms which have been discussed.

The cases illustrating my thesis were under observation for periods varying from three weeks to nine months.

1854 Race Street, November 1, 1890.

CLINICAL MEMORANDUM.

OPHTHALMOLOGICAL.

Two Cases of Foreign Body in the Eyeball.—These two cases, of recent occurrence, seem worthy of note, on account of the large size of the foreign bodies and the almost entire absence of pain:

P. J. M., machinist, aged thirty years, was struck in the left eye by a piece of cold chisel. The course of the offending body was marked by a nick in the edge of the lower lid, a cut in the lower outer quadrant of the cornea, and a ragged opening in the iris. There was considerable hæmorrhage into the anterior chamber and vitreous, but *absolutely no pain then or subsequently*. Immediate enucleation was advised and consented to by the patient, but his family objected. After two months of varied experiences he returned, and I removed the eyeball, which was softened and had shrunken to one-third its normal size. The bevelled edge of the chisel, about one-eighth of an inch wide and half an inch long, was found on the floor of the eye, imbedded in the degenerated vitreous.

George R., negro, aged ten years, came to me with an injury of the left eye. He said that a boy had fired a buckshot at him from a spring-gun used for killing sparrows. The edge of the lower lid was perforated, and there was a round hole in the lower and inner part of the eyeball, just below the sclero-corneal junction. There was considerable hæmorrhage, but *little or no*

pain then or afterward. On the supposition that the buckshot was in the eye, immediate enucleation was advised; but when the boy with the gun insisted that the end of the steel spring had done the injury, it was thought best to wait a few days. At the end of a week the eyeball had softened, and when removed was found to contain the metal end of a large shoestring that had been used for the bowstring of the gun. It was three-fourths of an inch long, and the sharp end was projecting slightly from the eyeball, a short distance below and outside of the entrance of the optic nerve. The sharp, arrow-like tip had transfixed the eye obliquely through the lower half.

HOSPITAL NOTES.

KENSINGTON HOSPITAL FOR WOMEN.

SERVICE OF CHARLES P. NOBLE, M.D.

[Reported by A. H. DEEKENS, M.D.]

A CASE OF INTRA-LIGAMENTARY CYST OF THE LEFT OVARY—ENUCLEATION; RECOVERY.

MRS. M., aged fifty-eight years, married, gave a history of abdominal enlargement dating from an attack of dysentery about a year previously. For six months she has had considerable discomfort in her abdomen, while for the last two months her abdomen has been enlarging quite rapidly, and with the increase in size the discomfort became more marked, though at no time has she complained of pain. She had passed the menopause five years before the abdominal enlargement appeared, and for four years enjoyed fairly good health.

Becoming alarmed at the rapid growth of the tumor, which had been complicated by a mild attack of peritonitis with considerable pain, she sent for her physician about a week previously. Dr. Noble saw her in consultation a few days later.

At this time she was stout and apparently fairly healthy, but had a very sallow complexion. She had not been confined to bed, as she said that she felt better when up than when lying down. Upon examination Dr. Noble found a large, hard, multinodular tumor, which nearly filled the abdomen, but was situated more to the right side than to the left. There was doubtful fluctuation. An operation was advised, and the patient entered the Kensington Hospital for Women on the following day, September 9th.

On September 13th, Dr. Noble, assisted by Dr. George M. Boyd, operated in the presence of a number of physicians. The operation proved to be quite a formidable one owing to the numerous adhesions and intimate connections of the tumor with the abdominal organs. A median incision, three inches in length, exposed a multilocular cyst. This was tapped and about eight quarts of the ordinary gelatinous fluid was discharged. The sac was now withdrawn and was found to be an intraligamentary cyst of the left ovary. Enucleation was begun by breaking through the peritoneum along the descending colon—the tumor had raised the peritoneum in this locality and was attached to the muscular wall of the colon. The adhesions were stripped or tied off, until the entire tumor was enucleated, and only a slight attachment to the peritoneum of the broad ligament, near the uterus, remained; this was transfixed, tied *en masse*, and separated from the cyst. A large cup-shaped cavity remained, which represented the original site of the tumor. All bleeding-points were searched for and secured, the pelvic cavity was thoroughly washed out with boiled water and sponged until dry, and a drainage-tube was then inserted and the incision closed.

The operation from the beginning of the incision to the tying of the last abdominal suture occupied an hour and twenty-three minutes. The cyst was aspirated in seven minutes and enucleated in fifty minutes. Chloroform was the anæsthetic used. The patient was put to bed with a pulse of 65. This slow pulse-rate was, perhaps, due to the tincture of digitalis which was given hypodermically during the operation.

The woman made an uninterrupted recovery. The drainage-tube was removed on the third day. On the sixth day she was able to sit up in bed, supported by a bed-rest, and the stitches were removed. On September 26th she was able to get out of bed, and on September 30th she walked down stairs on her way to the convalescent wards of the hospital.

Her temperature at no time rose above 100⅕° and was at that point for a brief period only. This elevation was due to constipation, which was relieved by glycerin enemata. Her pulse remained between 80 and 85, once running up to 94 for a short time.

This case is of interest, among other reasons because the patient had not suspected any growth until two months before the operation—she thought that she was merely "becoming fatter"—because there was very slight impairment of the general health, and because the character of the fluctuation was doubtful.

MEDICAL PROGRESS.

Pyoktanin in the Treatment of Gonorrhœa.—LINDSTOERM (*Vratch*, November, 1890) has tried pyoktanin in seventeen cases of gonorrhœa. When injected into the urethra in the strength of from 1 to 4 : 1000 it failed to alleviate the pain, but in all of the cases there was a diminution in the purulent secretion. In a number of cases of chancre he applied pyoktanin with powdered chalk in the proportion of from 1 to 2 : 1000, but found that the effects were no better than those generally obtained from the use of powdered calomel. As a consequence Lindstoerm is not very favorably impressed with the new antiseptic.

Sulphonal in Diabetes.—CASERELLI reports from the Clinic of Professor Grocco that the employment of 30 grains of sulphonal daily in diabetes produces marked diminution in the quantity of both the sugar and urine. He remarks, however, that too large doses of the sulphonal will produce disagreeable symptoms, such as vertigo and excessive somnolence.

Injections for Gonorrhœa in the Male.—LANG, of Vienna, employs injections two or three times daily in both the acute and chronic form of this affection. For acute gonorrhœa he recommends the use of a solution of sulpho carbolate of zinc of ¼, ½, or 1 per cent., the

quantity of liquid injected each time being 1½ drachms. For gleet the volume of the injection may be as much as from 2 to 3 drachms. Along with these injections he recommends careful diet, excluding all red meats, and as much rest as possible.

Treatment of Disseminated Acne.—According to Hertzmann, the following treatment is to be employed in cases of acne indurata et pustulosa. The pustule is to be evacuated and cauterized by introducing the tip of a piece of wood dipped in a solution of perchloride of iron, and frictions of the face are to be made with carbolic acid of the strength of 3 to 5 per cent., in water, and afterward

℞.—Salicylic acid . . . . 45 grains.
Alcohol (95 per cent.) . . 5 ounces.

is to be applied to the skin.

For acne papulosa, where the papules are small and numerous, frictions with tincture of green soap are very useful, the prescription being made up as follows:

℞.—Green soap . . . . 1 ounce.
Alcohol (95 per cent.) . . 2 ounces.
Spirit of lavender . . . ½ ounce.
Water . . . . . 3 ounces.

After this is applied vaseline or cold cream should be smeared over the skin. Where the disease is very severe the following prescription is advisable:

℞.—Naphthol . . . . . 2½ drachms.
Precipitated sulphur . . . 1½ ounces.
Lanolin and green soap, of each 2 "

For seborrhœic acne daily frictions with the following solution are useful:

℞.—Flowers of sulphur . . . 2 ounces.
Lime . . . . . 4 "
Water . . . . . 1 pint.

Boil, decant, and keep in a closed vessel. Should application of this medicament produce much irritation of the skin cold cream should be applied.

Tapping and Draining the Ventricles of the Brain.—Mr. A. W. Mayo Robson (*British Medical Journal*, December 6, 1890) reports a case of localized meningitis, with accumulation of fluid in the lateral ventricles, in a child aged ten years, that was successfully treated by tapping and draining the left lateral ventricle. The fissure of Rolando having been mapped out, the patient was anæsthetized with the A. C. E. mixture, a large semilunar flap was turned down, and the skull was trephined with a one-half inch trephine over the situation of the motor centre of the arm, there being right hemiplegia, aphasia, twitching of the arm, and tonic spasm of the thumb. On raising the dura, which appeared healthy, the surface of the brain was found to be compressed and not pulsating. The needle of an exploring syringe was then thrust deeply in various directions in the hope of finding pus. Failing to find any, the needle was thrust into the posterior extremity of the second frontal convolution and pushed transversely inward and slightly downward into the lateral ventricle. Six drachms of clear fluid escaped, after which the natural pulsations returned to the exposed portion of the brain. The dura was then sutured with fine catgut, several bone-grafts were placed over it, and the scalp was united, no drainage-tube being employed.

On the following day slight power of movement returned in the right arm and leg, and on the third day the patient could answer simple questions. Within a month all paretic symptoms disappeared. Six months later she was perfectly well, with the exception of occasional slight convulsive seizures, limited to the right arm and unaccompanied by loss of consciousness, which Mr. Robson thinks were possibly due to adhesions at the site of operation. Bromides were prescribed, and when the patient was last seen the attacks were only occasionally returning.

At the close of his remarks the author made a number of suggestions as to the *technique* of the operation, of which the following are the most important:

1. If there is time, a purgative should be given on the day before the operation.

2. The chief convolutions, the fissure of Rolando, and the base-line should be mapped out on the shaven scalp with nitrate of silver, a carbolic acid dressing should then be applied and allowed to remain until the time of the operation.

3. If an anæsthetic is required the A. C. E. mixture should be used.

4. In order not to lose the landmarks after the flap has been turned back, the scalp should be perforated by a small drill which will make a distinct mark on the skull.

5. In simple tapping of the ventricle the trephine-opening should be smaller than if a drainage-tube is to be used, and a linear incision, three-fourths of an inch long, in the scalp is sufficient.

6. If drainage is to be adopted the periosteum should be reflected from a circle slightly larger than the circumference of the trephine.

7. The needle or director should be removed and reintroduced for every new puncture, and the large vessels and important parts of the brain should be avoided.

8. The punctures should be made in the course of the fibres and vertical to the surface.

9. If a drainage-tube is to be left in, a fine director should be used, along which a pair of Lister sinus forceps can be pushed and the puncture dilated to receive the tube.

Ichthyol in the Treatment of Gonorrhœa. — Köster (*Wiener medizinische Presse*, November 23, 1890) writes enthusiastically of the use of a one-per-cent. solution of ammonium sulph-ichthyolate in gonorrhœa. He has used it in three cases of gonorrhœa in men and in one case of gonorrhœal cystitis in a woman. In the cases of gonorrhœa he employed injections of the solution three times daily. On the second day of treatment the painful micturition and the painful nocturnal erections disappeared. The discharge ceased permanently in from four to twenty days.

In the case of cystitis, in which the symptoms were severe, four and one-half ounces of the solution were injected twice daily for eight days by means of an irrigator, the solution being retained in the bladder for five minutes, and then permitted to escape through the urethra. After the second day of treatment the pus disappeared from the urine and there was no longer severe pain.

GOUTY AND RHEUMATIC EYES.

IT is a matter of common knowledge that not infrequently the existence of certain grave constitutional disorders is first discovered by an examination of the eye. The two most noteworthy examples of this fact are albuminuric retinitis in an individual believed to be in good health up to the time of its detection by an ophthalmoscopic examination made because of a complaint of dim vision; and optic neuritis in a person who, before the date of the ocular examination, was not known to be the subject of any of the complaints which may cause the appearance of papillitis. In these instances disease of the intra-ocular end of the optic nerve, or of the retina, leads to the discovery of either a general disease or a gross local lesion in the central nervous system.

In another group of cases some inflammatory disease of the eye precedes the development of the constitutional disorder; that is to say, this inflammation is a symptom that occurs sometimes days or even months in advance of the general outbreak. More than any other two diseases, gout and rheumatism have furnished examples in which the eye has thus become the index of what was to follow.

In a third class of cases the subject of an ocular complaint is attacked not because he himself is at the time afflicted with a constitutional disease in an active state, nor because the eye-symptom which has appeared is a sign that he will become affected with a general malady, but because he is by inheritance the subject of a disorder which makes its first manifestation in him as an inflammation of one or more of the coats of the eye. Leaving out of the question the syphilitic diseases of the eye acquired by inheritance, this class is typified by the remarkable series of cases of iritis almost invariably associated with disease of the vitreous occurring in children and young people, insidious in character and destructive in tendency, described by Mr. Hutchinson. These children of gouty parents, according to this observer, have a peculiar squareness of build, heavy features, florid complexions, and feebleness of the circulation in the extremities.

In the second group of cases the gouty and rheumatic diatheses may present ocular inflammations as their first manifestations, or, in other words, the disease of the eye may reveal these diatheses, previously latent and unsuspected. To this class TROUSSEAU (*L'Union Médicale*, No. 113, 1890) calls attention by the report of some striking examples. The type of these cases is an individual who, up to the age of twenty-five or thirty years, has been in good health; then is attacked with a subtle form of iritis or scleritis, and in spite of repeated questions on the part of the medical adviser the true nature of the malady is undetected until at some later date a manifestation of gout or rheumatism in some distant organ is perfectly evident. As an example Trousseau quotes the case of a patient who had a stubborn episcleritis, which relapsed time and again in spite of the use of salicylates of sodium and lithium, iodide of potassium, and tincture of guaiac. Frequent interrogation failed to extract any history of gout or rheumatism in the ancestors, and a minute examination discovered no trace of arthritic tendency in the patient himself. A continuous course of colchicin was without effect. The actual cautery was employed to arrest the disease, and later the patient was sent to Vichy, where, after some days' residence, he was violently attacked with an acute, frank gout, thus absolutely establishing the diagnosis which had so long remained obscure. As an illustration of the same principle, but more particularly of the fact that the first symptom of gout may appear in the eye, is seen in another case, a woman of twenty-five years, with an iritis associated with hæmorrhage into the anterior chamber, whose father

had been gouty, but who herself in her previous life never had suffered from any manifestation of this disease. Rapid improvement followed the administration of salicylate of sodium, but she was unwilling to believe in the gouty origin of her ocular trouble until six months after the cure of the iritis, when a characteristic inflammation of the great toe occurred, with a new attack of iritis. Again, a third case, a man aged forty-one years, without personal or ancestral gouty taint, developed an intense irido-choroiditis, for the explanation of which no satisfactory cause could be found until three months later, when a gouty inflammation of the articulations of the fingers of both hands appeared. Other cases are quoted illustrating how rheumatism may first appear in the eye, in some instances with no sign in either the system generally or in the family history to lead to a suspicion that this was the cause of the local inflammation, and be followed some months later by an attack of rheumatism elsewhere in the body.

Independently of the violent disorders with a tendency destructive to vision, like iritis, irido-choroiditis, vitreous opacities, and even neuro-retinitis, the result of gout, a very much milder inflammation, or rather irritation, may appear in the eye and prove a satisfactory index, if properly interpreted, of concealed gout. This disorder has been more aptly described by Mr. Hutchinson than by any other observer, and to him we are indebted for a name which exactly characterizes the most prominent symptom of the complaint, "hot eye"—which with scarcely an appreciable flush, with a burning sensation unrelieved by local measures, and often entirely unsuspected as far as its etiology is concerned, will worry the patient day in and day out until by accident or otherwise the gouty nature of the complaint is detected. A change in diet, a course of mineral waters, and, usually, some salt of lithium will effect a remarkable change.

The writer of the present note remembers well one woman who several times a year was attacked in the manner just described, who had sought relief in all manner of ways, whose eyes had been douched with various collyria and burdened with all kinds of spectacles, and who barely escaped a graduated tenotomy, when two of her relatives on the paternal side were sent for, one of whom had much deformed fingers, the result of gouty deposits in the joints, and the other a gouty inflammation of the tympanic membrane. The riddle was solved and appropriate constitutional treatment relieved this and all subsequent attacks.

We have called attention to these facts which have so frequently been dwelt upon by Mr. Hutchinson and others, and which are again referred to by Trousseau, because they seem in spite of repetition not always to have made enough impression to result in accurate diagnosis. More than this, they are good examples of the fact that a clinical history alone, however carefully taken, should not be sufficient to eliminate from the mind of the examiner the suspicion of diatheses the presence of which his questioning has failed to reveal, and that in a doubtful case it is well to examine the relatives of the patient under treatment.

SPECIAL ARTICLE.

A SECOND CONTRIBUTION ON THE TREATMENT OF TUBERCULAR DISEASE, BY KOCH'S METHOD, IN ST. LUKE'S HOSPITAL, NEW YORK.

BY FRANCIS P. KINNICUTT, M.D.,
PHYSICIAN TO ST. LUKE'S HOSPITAL, NEW YORK.

AT the end of the second week of investigation of the treatment of tubercular disease by inoculation with Koch's lymph, in the wards of St. Luke's Hospital, the first profound impressions made upon the observer of its potency and elective affinities have only been strengthened.

As a thorough clininal study of a larger number of cases would be impossible, only seven new patients have been inoculated, making the total number of cases at present under treatment twenty-two. The new cases are as follows:

One case of aggravated eczema of the hands, orbicular in form, inoculated as a control-experiment; one case of lupus of the uvula and contiguous portions of the throat; one case of tubercular glands (cervical and submaxillary), with doubtful signs of infiltration at the apex of one lung; one case of epithelioma of the hand, inoculated with the view of studying the possible effect of treatment; one case of tubercular disease of the ankle-joint; one of hip-joint disease: and one of pulmonary tuberculosis in its incipient stage. The rule has been maintained of making use of 0.001 gramme for the initial inoculation in adults, of 0.0005 gramme in children. The rule is also adopted of continuing the same dosage until reaction ceases to be developed, and of increasing its strength by 0.001 gramme successively as reaction ceases to appear. In cases of lupus, Koch's suggestion that inoculations be given at intervals of a week or longer—that is, only after local reaction has subsided—is now followed.

The observation has been made that the systemic

disturbances in this disease are less severe than those exhibited in other forms of tubercular disease, the inoculations being of similar strength; inasmuch as the reaction in several instances has been delayed as late as twenty-four hours, and has then been characteristic, daily inoculations are not given in any instance. Local irritation at the site of the inoculations has not occurred in any of the cases.

The possibility of obtaining equally good results with a smaller amount of lymph than that used by German investigators has apparently been demonstrated (0.004 gramme is the largest dose used in any case). By this we see that the distressing, if not grave, symptoms of very acute reactions may be avoided. The marked systemic disturbance, aside from the rise in temperature, in a number of patients treated with *small* doses, has been impressive, and has suggested caution in treatment. The appearance and condition of the patient during the period of reaction in many instances have been suggestive of the presence of an acute infectious disease. A low arterial tension has obtained as a rule. The records subsequent to the third inoculation of the three patients whose histories were given in The Medical News of December 20th, are appended. The histories of two patients, suffering respectively from incipient hip-joint disease and tubercular osteitis of the ankle-joint, have also been selected for the present report, as presenting points of great interest.

Case I. (*Continued from page 643.*) *Tubercular infiltration of apex of right lung.*—Third inoculation, December 16th, 0.001 gramme. Reaction developed six hours later. Duration of reaction, thirty hours. Highest temperature 103.8° F., eighteen hours after inoculation. Amount of sputa, two ounces. Physical signs: Numerous moist râles in large tubes of affected area, abundant moist crepitation; no appreciable enlargement of spleen. Re-inoculations were made on the 20th and 23d; the reactions being very similar to those previously described. The physical signs observed at the present date are markedly different from those present prior to the first inoculation. They consist in a distinct increase in the moist crepitation, which is heard over a decidedly larger area, associated with large mucous râles and an extension of the limits of broncho-vesicular respiration. The inference is that tubercular infiltration was more extensive than was appreciable by physical signs.

Case II. (*Continued from page 644.*) *Prostatic surface tubercular disease.*—Third inoculation, December 16th, 0.001 gramme. Reaction developed five hours later. Duration of reaction, twenty-nine hours. Highest temperature 103.8° F. Local signs: Severe pain felt at base of penis. Great irritability of bladder, the urine being ejected every fifteen or twenty minutes through supra-pubic opening (made previous to admission).

Re-inoculations were made on December 19th and 23d, 0.001 gramme, with the development of reactions very similar to those previously obtained. The only appreciable difference in the patient's symptoms before the first inoculation and at present, consists in the greater freedom from pain in the urethra in passing water.

Case III. (*Continued from page 644.*) *Lupus of the ear and contiguous portions of the face and neck of twelve years' duration.*—Third inoculation, December 16th, 0.003 gramme. Reaction developed six hours later. Duration of reaction, thirty hours. Highest temperature 103.8° F. Local signs: Very considerable sero-purulent exudation, which crusts rapidly; crusts cover nearly the entire affected area. A hyperæmic areola more than an inch in width surrounds the entire patch. Posterior margin of patch presents a raw fissure, as if the morbid tissue were separating from the healthy skin. It was deemed advisable to permit all local reaction to subside before further inoculations, and none has been made since. The present appearance of the diseased tissue is described by Dr. George H. Fox as follows:

December 22. The crusts having been removed by the application of cotton soaked in oil, the affected part appeared red and smooth, and the cicatricial lines from previous scarification are again apparent. There is a purulent secretion behind and below the ear. The whole ear feels softer; this is especially true of the lobe, which, aside from being hyperæmic, has a normal appearance and feel.

Case IV. *Incipient hip-joint disease.*—Female, aged six years, in the service of Dr. Newton M. Shaffer, at the New York Orthopedic Dispensary from November 9, 1890, until admission to St. Luke's Hospital. Previous history: Patient had been noticed to limp for three weeks, and had had "night cries" for about the same period.

Examination showed the characteristic limp, attitude, and reflex muscular protection of the joint.

Although these signs were not of the most prominent type, a diagnosis of incipient hip-joint disease was made by Drs. Samuel Ketch and Newton M. Shaffer, after a very careful examination. A long traction-splint was applied. Admitted to St. Luke's Hospital December 17th. Dr. Shaffer, at my request, has very kindly made daily examinations of the patient, and all further reports of the joint-signs are given in his own words.

Examination by Dr. Shaffer immediately before first inoculation: Patient has no pain, walks with a perceptible limp, the thigh being slightly flexed in locomotion. Examination of joint shows no perceptible swelling. The inguinal fossa on right side not quite so pronounced as on the left. Concussion of the hip-joint gives no pain. There is no deformity present, the flexion above noted disappearing when patient is recumbent. The tests, as applied to the movements of the affected hip, resulted as follows:

Flexion markedly resisted about 10° short of full flexion. When this point is reached the patient "flinches" very decidedly, as is also the case in *abduction* and *adduction* of the thigh, both these movements being limited by reflex muscular spasm

a few degrees short of normal. With the thigh flexed to about 135° *rotation in* is very markedly resisted. *Rotation out* in same position resisted only in the extreme. With patient prone, extension of thigh (pelvis being held firmly) is quite noticeably resisted. In this position both *rotation in* and *rotation out* are very much restricted. In all these tests the patient "flinched" very plainly when it was attempted to pass beyond the point indicated by the instinctive muscular protection.

December 17, 1890, 3.30 P. M. First inoculation, 0.0005 gramme. Temperature normal. Reaction developed eight hours later. Duration of reaction, thirty-seven hours. Highest temperature 103° F.

18th. Twenty-four hours later. Hip-joint in position characteristic of hip-joint disease in the *second stage*—that is, the thigh is abducted, apparently elongated, flexed and rotated outward. The joint is very sensitive, the slightest attempt at motion giving pain. By using great care 10° of lateral movement (in abduction and adduction) can be demonstrated. There is a movement of flexion of only 15°. No rotation can be demonstrated. The inguinal fossa is obliterated and there is œdema of posterior swelling. The deformity present was as follows: Thigh flexed at 15°; abduction 20°; rotation out about 30°.

The following peculiar condition was noted, unlike that found in morbus coxæ, in the acute stage. The patient noticed no difference between crowding the joint surfaces together and on making traction on the joint. Each test produced pain and there was no relief from traction.

19th. Joint movements much changed for the better; all movements of the joint can now be made, but they are still greatly restricted. *Deformity:* Flexion 160°; abduction *nil.* Rotation in and out still restricted. Rotation in gives pain. Patient still notices no difference between pressure and traction upon the joint. Swelling still present.

20th. Joint movements very much like those of yesterday. The same may be said of the deformity. Joint can be handled with much freedom. Inguinal fossa still obliterated.

Second inoculation, Dec. 20th, 0.0005 gramme. Temperature normal. Only very slight reaction developed eleven hours later. Duration of reaction, eighteen hours. Highest temperature 100° F.

21st. Twenty-four hours later, motion in joint is more free than yesterday, except in adduction, which can be made of 5°, rotation still being limited. Inguinal glands can be made out. *Deformity:* Flexion 135°. Rotation out unchanged. Muscular resistance at joint well marked. Tenderness of joint diminished.

22d. Examination at 5 o'clock, P.M., Dr. Thomas L. Stedman being present. The following movements of the joint are normal, viz., flexion, abduction, and rotation out. Rotation in, extension, and adduction are approximately normal. Rotation *in* during flexion is slightly resisted.

Another important condition was noted at the examination. The character of the muscular resistance is unlike that observed at the examination of December 17th. The peculiar instinctively muscular check which accompanies hip-joint disease, and which was noticed on December 17th, has disappeared. The muscular resistance to-day can be overcome by gradual and gentle pressure, without pain or flinching, and that which appeared to be a fixed resistance to joint movement disappears. The joint can be handled with freedom without inflicting any pain at all. Still some swelling in inguinal fossa.

Remarks.—There are four points that seem very instructive. 1st. The diagnostic value of the lymph; 2d. The immediate and wonderful changes produced in all the signs and symptoms; 3d. The fact that though the joint was acutely painful traction gave no relief; 4th. The great change in the character of the muscular protection of the joint. It was deemed best to use the long traction-splint during the treatment, and the immobilization produced by it was of great comfort to the patient. The future history of the patient will be watched with great interest.

Case V. *Tubercular osteitis of ankle-joint.*—Male, aged six years. Patient under care of Dr. Newton Schaffer in out-patient department of Orthopedic Hospital since 1889. During this period improvement. On admission to St. Luke's Hospital, examination by Dr. Shaffer before first inoculation as follows: Slight thickening about joint; ankle extended to 100°; motion about 3° or 4°; reflex spasm marked; no pain on ordinary manipulation.

December 17. First inoculation, 0.0005 gramme. Temperature normal. Reaction developed ten hours later. Duration of reaction, forty-one hours. Highest temperature 102° F.

18th. Examination by Dr. Shaffer. Joint slightly swollen. Sensitiveness increased. Reflex spasm more marked and more alert.

19th. Joint condition improved; sensitiveness less, though marked when attempt made to flex the joint. Swelling less. Improvement in the equinus deformity.

29th. Second inoculation, 0.0005 gramme. Reaction very similar to that subsequent to first inoculation. Highest temperature 102.3° F.

22d. Examination by Dr Shaffer. Motion of joint distinctly improved. No pain unless some force is used in flexion. Surface temperature about normal.

FURTHER REPORT ON KOCH'S LYMPH.

By WILLIAM OSLER, M.D.,
Professor of the Principles and Practice of Medicine in the Johns Hopkins Hospital.

The cases under treatment by Koch's method are progressing favorably. In my wards there are eight selected cases of pulmonary tuberculosis and two of tuberculous pleurisy. The dose in the phthisis cases has been gradually increased, and some of the patients received to-day (December 22d) 1 c.c. of the one-per-cent. solution. Although

the febrile reaction in each instance was prompt and definite after the first or second injection, the subsequent inoculations have not been followed by any special febrile reaction, even with the larger quantities injected. There has usually been an increase in the cough, and in several cases a marked increase in the expectoration. A special feature in three of the cases has been the enormous increase in the bacilli in the sputa. The ordinary cover-glass preparation looked, in some instances, as if taken from a pure culture. The change in the appearance of the bacilli, which has been noted by many observers, is quite marked. No definite alterations have, as yet, been detected in the physical signs. In the tuberculous pleurisy, the reaction has been much more intense than in the pulmonary cases.

A very wholesome dread of the treatment has been aroused in the community by the newspaper reports of death. It is remarkable that there have been not more than two or three voluntary applications at the hospital, and several very suitable early cases, which were sent for, refused to subject themment until the method had been more fully tried.

On the surgical side, Dr. Halstead has five cases of bone and joint tuberculosis under treatment, and one of lupus, which has displayed all the characteristic phenomena so often described. In surgical tuberculosis the reaction has been in each instance much more intense than in the phthisis cases.

In Dr. Kelly's ward a case of tuberculous peritonitis is under treatment. The patient some months ago had the tubes removed and at the operation the peritoneum was found covered with tubercles. A condition of tuberculous salpingitis existed. She made a good recovery and left the hospital with a small sinus at the lower end of the abdominal incision. After the injection of one-tenth c. c. of the one-per-cent. solution she had intense febrile reaction, reaching to 104°, and the abdomen became tender and slightly swollen. There was no increase in the discharge from the sinus and no swelling of its walls. The fever kept up for three days.

In the pathological laboratory, Professor Welch and Dr. Nutall are making careful studies of the changes in the bacilli and have instituted a series of experiments on guinea-pigs with the sputa of the patients under treatment.

SUMMARY OF TWENTY-ONE CASES TREATED BY KOCH'S LYMPH AT THE MONTEFIORE HOME FOR CHRONIC INVALIDS.

BY SIMON BARUCH, M.D.,
OF NEW YORK.

My data refer to seventy-one injections in twelve male and nine female patients.

The reaction was undoubted in every case, although somewhat less than is announced from abroad.

Several of the cases, male and female, whose temperature had been normal, presented a rise of one to two degrees just before the injection.

Every case of phthisis presented a rise of temperature within twenty-four hours.

In one case of caries of the vertebra, with pneumothorax, the temperature also went up two degrees.

One case of ulceration (of doubtful type) in the left cervical region, with fistulous canal, resisted gradually-advancing injections until 5 mg. were reached, when the temperature rose from 97.8° to 102.4°. To-day it is again 97.4°. There is an increase in the discharge now; no change in patient's general condition.

A jaundiced hue of the skin was noticed in one case of phthisis; also nosebleed, headache, and nausea. Cough and expectoration increased in four cases, was diminished in ten cases, remained the same in six, and appeared anew in one regarded as cured.

Decided nausea and headache occurred in eleven cases.

Every case reached a normal temperature once or oftener in the course of twenty-four hours.

Pulse: The lowest pulse-rate was 44, the highest 134.

Respiration: The lowest recorded was 17, the highest 45.

Temperature: The lowest recorded was 97.4°, the highest 103.2°.

Weight: Of eight patients weighed, one lost one-half pound, one lost one pound, one gained three-quarters of a pound, one gained one-half pound. The others are unchanged.

The most remarkable point in my experience is that in two cases—which were almost ready to be discharged on account of abeyance of symptoms and physical signs, and a gain of weight of twenty-one pounds in one and of thirteen and one-half pounds in the other, under hydrotherapy—one lost one pound and the other three-quarters of a pound since the injection.

These cases would have been regarded as practically cured, had not the injection of 1 mg. of lymph caused decided reaction. One of these cases is, perhaps, more completely prostrated by the lymph than any other. I regard this experience as a complete vindication of Koch's view of the diagnostic value of the injection in suspected tuberculosis.

47 E. SIXTIETH ST., Dec. 23, 1890.

CORRESPONDENCE.

PSOROSPERMOSIS.

To the Editor of THE MEDICAL NEWS,

SIR: In your esteemed journal of November 8th there appeared a clinical lecture by Dr. L. D. Bulkley

on *Psorospermosis follicularis cutis*, delivered on October 8th.

The case presented and described is the same one upon which I based my communication to the International Congress in Berlin, August 12, 1890 (*Annales de Dermatologie et Syphilographie*, 1890, p. 707), and which I, together with Dr. L. Weiss, also presented by invitation at the September meeting of the New York Dermatological Society, and was allowed to submit my microscopical preparations for the inspection of the members.

Dr. Bulkley admits the identity, and says in his article: "I am told that Dr. Lustgarten, of New York, gave this patient's disease its present (and probably correct) name and exhibited microscopical sections of the same at the recent Congress in Berlin." It is hardly in accordance with this admission that Dr. Bulkley publishes the case, and it is decidedly unwarranted that in the enumeration of the few hitherto recorded cases he speaks of this case as "my own" and "Case 6 (Bulkley)." As professional custom gives the claim of a case to the man who was the first to diagnose and to describe it, as everyone is well aware, it is evident that the right in this case of literary ownership belongs to me. I can only presume that this gross violation of professional etiquette is based upon an oversight on the part of Dr. Bulkley, which I expect he will rectify by renouncing in your journal the claim which he has put forth.

Respectfully, S. Lustgarten, M.D.

PARIS.

French Opinions on Koch's Treatment.

At the meeting of the Société Médicale de Paris, December 8th, which is exclusively composed of hospital physicians, communications were read by Drs. Ferrand, Cuffer, and Chibierge, members of the Society who had been to Berlin for the purpose of observing Koch's investigations. So as to be able to watch the experiments closely, these three gentlemen divided their task into three classes: Dr. Ferrand studied more especially the general action of Koch's remedy, Dr. Cuffer devoted himself to the influence of the remedy in cases of phthisis, while Dr. Chibierge took up the treatment of lupus. All these gentlemen, before making their communications, expressed their thanks for the highly courteous manner in which they were received.

Dr. Ferrand then began on the general action of the remedy. His conclusions are that Koch's agent is capable of producing an elevation of temperature, and that, locally, it excites congestion, which is most marked in tubercular tissues. If one considers the physiological perturbation brought on by Koch's lymph, it is seen taht the effects are comparable to those of a muscle-poison; for symptoms occur which show that the muscular fibres which control the vessels have been paralyzed, and the heart itself, the muscular organ *par excellence*, is involved.

As to the contra-indications of Koch's method in pulmonary phthisis, they are, according to Dr. Ferrand, first, extensive invasion by the tubercular lesions; second, great weakness of the patient, or an adynamic condition; third, previous pulmonary hæmorrhages; and, fourth, high temperature.

Dr. Senator, of Berlin, says that Dr. Ferrand is the first one to notice these contra-indications, which very much restrict the field of action of Koch's lymph in pulmonary tuberculosis. Dr. Ferrand closed by saying that no fact as yet observed allows one to attribute to this mysterious remedy a curative action on phthisis.

Dr. Cuffer, who spoke next, recommends all to be on their guard while using the remedy. He has observed several phthisical patients who did not show a trace of reaction after the injection. These cases are, it is true, very few, but sufficient to establish the fact that Koch went a little too far in his first celebrated communication, in which he maintained that whenever he had to deal with a tubercular patient, the injection of his lymph would produce a well-marked reaction. But, besides this, there is a more important fact, namely, that the local reaction produced by the lymph is not always temporary. In Professor Senator's wards Dr. Cuffer has seen several cases of pulmonary phthisis that progressed very rapidly after the treatment, notwithstanding the fact that the injections were made with the greatest possible care. A case of acute phthisis, accompanied by very high fever, sank rapidly as a result of the injections. In other cases there was great aggravation, and the auscultatory symptoms of pulmonary softening increased, as well as the number of bacilli in the sputum. The same bad results have followed the use of the remedy in pleurisy. In one case the patient presented only a slight pleuritic area at the base of the left lung. The first inoculation was followed by extreme prostration and pain so severe in character that for some time Professor Senator thought that he had to deal with pleural and pulmonary gangrene. The author also said that the accidents of the reaction following the injections signify a very intense congestion, and probably, in some cases, acceleration of the pulmonary disease; moreover, complications have been observed in the liver and kidneys, and also albuminuria. Many years ago, the late Professor Lasègue, of Paris, showed how greatly tuberculosis may be accelerated by albuminuria. Dr. Cuffer closed by saying that great improvement following the injection has been announced by some physicians, but that he, during his stay in Berlin, did not see one case in which he could really say there had been improvement, while, on the other hand, cases of aggravation are undeniable.

He thinks that to obtain the best results from Koch's lymph in cases of consumption, provided this remedy is of any use, the proper doses must be carefully studied, and must vary according to the degree of the tubercular lesion, and also according to the resisting power of the patient, his temperament, and whether or not he is subject to congestions. Dr. Cuffer also thinks that to moderate the congestions which occur after injections an anti-congestive and astringent medication should be resorted to.

The effects of the treatment on external tuberculosis as represented by lupus, were next reviewed by Dr. Chibierge, who has had a large experience with tuberculosis of the skin. He said that Koch's lymph produces very intense and peculiar reactive phenomena at the seat of the lupus. It is not certain that these phenomena are curative. During his stay in Berlin he did not see a single case of lupus that was cured, even in patients who had been treated for two months. In a case which was

presented as an example of cure, Dr. Chibierge very easily discovered small nodules which were unmistakably lupus-tubercles. The author said that it was very strange that patients suffering from lupus, instead of being placed under the care of specialists in skin-diseases, were placed in medical or surgical wards, or even private clinics. The head of one of these clinics even acknowledged that before becoming an associate of Koch he had never seen a case of lupus. Dr. Chibierge does not say that Koch's method is useless in the treatment of lupus, for he, like others, has noticed the marvellously rapid action of the remedy, and its cicatrizing influence on extensive and rebellious tuberculosis; but he insisted that no one in Berlin was able to show him a single case of cure, or even an apparent cure, and that, on the contrary, he has seen a recurrence and increase of the disease in cases which had been considered as cured. He also advised that the remedy should be used with the utmost care, and never without having obtained the patient's consent.

NEWS ITEMS.

The Characteristic Organism of Cancer.—In an address before the Pathological Society of London on December 2d, and the Medico-Chirurgical Society of Edinburgh on December 3, 1890, Dr. William Russell stated he had been occupied for some years in tracing the mode of growth of cancer in different organs. By this study he hoped to map out the steps of the process, and by learning the manner of its growth to obtain perhaps an insight into the factors determining the departure of the tissues from their normal behavior and arrangements. He had found appearances which he could not fit into modes of cell-growth and nuclear proliferation, and these had so puzzled him in one case that he asked his pathological assistant, Mr. W. F. Robertson, to experiment on it with every possible combination of stains with a view to the possible differentiation of some of these structures. His attempts were soon successful by the following method: 1. Saturated solution of fuchsine in a two per cent. carbolic acid in water. 2. One-per-cent. solution of iodine-green (Grüber's) in a two per cent. carbolic acid in water. Place section in water. Then stain in fuchsine for ten minutes or longer; wash for a few minutes in water. Then wash for half a minute in absolute alcohol. From this put the section into the solution of iodine-green, and allow it to remain well spread out for five minutes. From this rapidly dehydrate in absolute alcohol, pass through oil of cloves, and mount in balsam. By this method it was found that certain structures stained a brilliant purplish-red, while the tissues stained green. Similar bodies were found in a number of cancers then examined, and these, for laboratory purposes, were called "fuchsine bodies."

With this discovery all kinds of possible errors suggested themselves. That they were not accidental impurities in material, bottles, or stains was shown by the fact that tissues from the same bottles and cut at the same time gave no indication of this. That they were not the nuclei of tissue-cells in exaggerated reproductive activity was tested by the cells in organized inflammation of serous membranes not giving the reaction, nor the cells in tubercle, in typhoid lesion, in inflammatory affections, or in the organs of an embryo. That they were not globes of some degenerative substance was proved by the examination of a great variety of tissues showing different varieties of degeneration. Further, they were not present in the sarcomata, nor in simple tumors, such as fibromata, papillomata, myomata, etc., nor in venereal warts and condylomata, nor in primary syphilitic sores. Sections of a tumor labelled adenoma of the mamma, and rich in adenomatous structures, and a gumma of the dura mater showed the bodies, but of the history of these cases he was ignorant. Another syphilitic case which had defied treatment, and in which there was extensive destructive lesion of the fauces and larynx and the bones of the vertebra behind the fauces, showed a few fuchsine bodies in sections of the larynx. Altogether tissues had been examined from fifty to sixty different cases selected with the purpose of subjecting the positive observations to the severest possible tests. The result was that fuchsine bodies were found in one case of chronic ulcer of the leg, one of tubercular disease of a joint with old sinuses, one of phenomenally severe, destructive, and intractable syphilitic lesion; and in two other cases, of which he had no record—one a case of mammary adenoma, and one a gummatous tumor of the meninges. He indicated possible explanations of these, and that they could not be regarded as sufficient to overthrow the other evidence.

Turning to the positive side of the question, forty-five cases of cancer had been examined, which included malignant epithelial growths of various structure, as epitheliomas of the lips and face, rodent ulcer, scirrhus of the mamma, both primary and recurrent; malignant adenoma of cervical glands, cancers of the stomach, liver, spleen, abdominal glands, supra-renal capsules, uterus, and ovaries. The pathological position of one of these was still uncertain; another was represented by sections dated 1885; in these two no fuchsine bodies were found, but in the remaining forty-three they were present. In individual sections they varied greatly in number, and it was noted that they occurred in special abundance in foci. They might be present in the small-celled infiltration at the margin of the cancer, among or in the epithelial cells, in the stroma, or in the lymphatics. As a rule, they occurred in clusters or groups of two, ten, twenty, or more, and they almost always showed a clear space round them. In shape they were perfectly round. The commonest size was 4 μ, but they might be much smaller or larger. Examined by daylight they appeared homogeneous and structureless.

As there seemed to be no escape from regarding these structures as special organisms, which—so far, at least, as his pathological material was concerned—were practically confined to cancer, the question was, Were they animal or vegetable, and what was their mode of growth and reproduction? To answer this question it was necessary to consider the work which had been done, especially on the Continent, in the study of cancer. He then referred briefly and in detail to the various papers which had appeared in French and German literature, in which it was contended that an animal parasite had been found in some cases of cancer. Summing this up and excluding molluscum contagiosum, it was found that Albarran, Darier, Thoma, Wickham, and Sjöbring

had found in cancer an organism which they described as belonging to the protozoa, while Thoma did not commit himself and only Wickham and Sjöbring give figures to aid in forming a judgment on their contentions. He next pointed out the characters of the protozoa, more especially the psorospermiæ or coccidiæ, and indicated that according to the authorities these were unicellular organisms forming in their interior psorospermiæ, which, in turn, developed spores which were usually sickle-shaped bodies, and became free parasites. To meet the necessity of this stage in their life, Sjöbring had figured the spore-formation in the cancers he examined. In short, looking at the work on this subject in the concrete, he regarded some of the figures as having nothing whatever to do with foreign organisms, that others were certainly misinterpreted, while some probably represented the organism with which he was dealing.

Returning to the consideration of the fuchsine bodies, they might be studied by the special method of staining given, or by logwood and eosine, or by Gram's methed with methyl-violet. Each group and most of the isolated individuals were surrounded by a clear area, often having the appearance of being bounded by a definite capsule. In so far as the isolated individuals were concerned one entered an epithelial cell, the protoplasm and the nucleus of which stained with logwood; while the foreign organism lay in a clear area or vacuole in the cell-protoplasm, to which there was no true capsule. Both in the epithelial masses and the vacuoles referred to there might in addition be small fuchsine bodies surrounded by a clear space, and bounded by a capsule or limiting structure. Further, it was to be noted that in the vacuoles there might be several fuchsine bodies; while in others the fuchsine body was granular and had lost its characteristic staining reaction, and showed undoubted spores in its interior. In the epithelium it may also be noted that some fuchsine bodies are surrounded by a vacuole, while others are not.

From the foregoing it might be contended that the organism in question was a protozoon, were it not that in sections stained by Gram's method the mode of repro duction is shown quite diagrammatically. The large fuchsine body is seen to give out a small globular body which increases its distance from the parent body, but remains attached to it by a filament; this bud grows and gives off another and a short chain, or other forms may be produced. The small spores could also be seen in the interior of the lymphoid cells, or leucocytes in the infiltrated area, the effect of this being to clear up the protoplasm of the cell and to produce a clear space or vacuole with a limiting ring.

This, he thought, was the mode of formation of what might be called the free encapsuled organism present among epithelial cells or lying in vacuoles. As to the appearances in the interior of epithelial cells, the foreign body at first had no vacuole round it, but ultimately developed one, and this was to be accounted for by its influence upon the surrounding protoplasm leading to its classification. He said that there could be absolutely no doubt that the organism was a fungus which belonged to the sprouting fungi—*Sprosspilze*—of Nägelë; but the proof of this was not to be readily found in every section, for the usual arrangement was in clusters, especially as demonstrable by the fuchsine and iodine-green method, which, he thought, acted best when the organism was at a certain stage of its growth.

In conclusion, he said that if the presence of this parasitic fungus in cancer was confirmed by other observers, we had found in it an organism whose nutrition, reproduction, and death in the tissue could hardly be conceived as occurring without producing changes fully equal to the anatomical changes present in cancer.—*Lancet*, December 13, 1890.

Rush Medical College.—A matter that has resulted in the retirement of Dr. Nicholas Senn, of Milwaukee, from the faculty of the Rush Medical College, of Chicago, has caused a number of students at that institution to make pilgrimages to Milwaukee during the past few days. It may be said at the outset that the students are all with Dr. Senn, and that they unanimously desire him to remain at the college. Dr. Senn has for three years been professor of the practice of surgery and surgical pathology at this school. Dr. Charles T. Parkes, who has been a member of the college faculty for about twenty years, is professor of the principles and practice of surgery, and he and Dr. Senn have really filled one professorship, but Dr. Parkes has had charge of the clinical work, while Dr. Senn's instruction has been given almost entirely in the form of lectures. Dr. Senn gave notice that unless he was permitted to take a hand in the clinical work, and give practical demonstrations as well as lectures, he would retire. To this Dr. Parkes strenuously objected, declaring that no one but himself "shall ever handle the knife in the clinic-room of this college." Dr. Parkes holds a large amount of stock in the college corporation and his influence with the faculty is considerable, while Dr. Senn owns no stock whatever.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING DECEMBER 20, 1890.

Evans, Sheldon G., *Assistant Surgeon.*—Ordered to the Naval Academy, Annapolis, Md.

Decker, Corbin J., *Passed Assistant Surgeon.*—Detached from the Naval Academy, and ordered to the Naval Hospital, Philadelphia, Pa.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FROM DECEMBER 8 TO DECEMBER 20, 1890.

Wyman, Walter, *Surgeon.*—Granted leave of absence for twenty days, December 11, 1890. To attend meeting of American Public Health Association, December 12, 1890.

Long, W. H., *Surgeon.*—Granted leave of absence for seven days, December 20, 1890.

Murray, R. D., *Surgeon.*—Granted leave of absence for thirty days, December 20, 1890.

Irwin, Fairfax, *Surgeon.*—Detailed for special temporary duty at Marine-Hospital Bureau, December 10, 1890.

Carter, H. R., *Passed Assistant Surgeon.*—To attend meeting of American Public Health Association, December 11, 1890.

Wasdin, Eugene, *Passed Assistant Surgeon.*—To attend meeting of American Public Health Association, December 11, 1890.

Kinyoun, J. J., *Passed Assistant Surgeon.*—Granted leave of absence for thirty days, with permission to go abroad, December 11, 1890.

Geddings, H. D., *Assistant Surgeon.*—Upon expiration of leave, to proceed to New York City for temporary duty, December 18, 1890.
